SUMMARY

Detailed knowledge of the past climate and environmental variability is vital in order to predict future scenarios with more confidence. High resolution and highly-resolved natural archives are therefore in growing demand (PAGES report, 2009).

This thesis is part of a coordinated effort, STALCLIM project, where a series of state-of-the-art methods in speleothems proxies were used in order to develop the full potential of speleothems as paleoclimate and paleoenvironmental archive. The thesis investigates climate variations as recorded by speleothems from Schafsfloch and Milandre caves, spanning time intervals of high scientific interest: 0 to 14 550 years BP and 130 000 to 230 000 years BP. The locations of the caves, Jura Mountains and the Alpstein Mountains (Swiss Alps) are regions highly sensitive to climate-induced changes in temperature, atmospheric pathways and/or environment evolution. In order to establish new climate records and resolve the paleoclimate questions, continuous geochemical analyses were applied, with high resolution stable isotopic and trace elements analysis and ^{230}Th age measurements, and these were combined with thin section analysis of the calcite petrology. Where possible, we conducted continuous and temporal measurements in the caves where the samples were collected, to provide a better understanding of the cave environment.

Chapters 2 and 3 highlight the sensitivity of high altitude speleothem proxies to small changes in temperature and water availability, both induced by internal and external climate drivers. The MF3 stalagmite, from Schafsfloch Cave, provides a unique opportunity to investigate a regional expression of millennial-scale climate variability in Central Europe during MIS 6 and Late MIS 7. The sample records in high detail the structure of the penultimate deglaciation in the Alps, and brings new evidence regarding the nature of this important climatic transition.

Chapters 4 and 5 show the high resolution composite $\delta^{18}\text{O}$ record and elemental composition of speleothems from Milandre Cave, covering the Lateglacial- Holocene interval. A detailed comparison with Greenland ice cores and Gerzensee lake sediments (Central Switzerland) indicates similarities in the long timescale changes of atmospheric circulation patterns in the whole North Atlantic region after the last deglaciation. In contrast, during the Holocene, the signature pattern in the isotopic calcite $\delta^{18}\text{O}$ data differs to that seen in Central Europe. This provides important insights into the regional teleconnections and local environmental reaction to changes in the temperature, seasonality of precipitation and atmospheric processes. The use of a robust $\delta^{18}\text{O}$ /temperature transfer function has enabled a high resolution temperature reconstruction of the autumn to spring temperatures at the Milandre site for the last 14 550 y BP.

In summary, this thesis provides new results on environmental and climatic variability in Switzerland during specific intervals over the last 230 000 years. It supports large teleconnections over the northern hemisphere and emphasizes the role of insolation and obliquity as important climate triggers in the region. These new high-resolution and precisely dated records of $\delta^{18}\text{O}$ and cold season temperature reconstruction for the Jura Mountains over the last 14 550 y BP, are proposed as being representative for Central Europe.

Das Wissen um das Klima der Vergangenheit und der Umweltvariabilität ist eminent wichtig, um zukünftige Szenarien besser voraussagen zu können. Dementsprechend sind hochauflösende natürliche Archive immer mehr gefragt (PAGES report, 2009).

Diese Dissertation ist ein Teil eines koordinierten Projektes (STALCLIM), in welchem moderne Methoden an Speläothem-Proxies benutzt wurden, um das volle Potential der Tropfsteine als paläoklimatisches Archiv zu entwickeln. Die Arbeit untersucht Klimavariationen, die in Tropfsteinen vom Schafloch und der Milandre-Höhle gespeichert wurden und die zeitlich hochinteressant sind: 0-14 550 Jahre sowie 130 000 -250 000 Jahre vor heute. Der Jura und der Alpstein, wo die Höhlen liegen, sind Regionen, die sensibel auf klimabedingte Änderungen in Temperatur, atmosphärische Zirkulationen und/oder Entwicklungen der Umwelt reagieren. Um neue Klimadaten zu erhalten, wurden kontinuierliche geochemische Analysen, hochauflösende Stabilisotopen- und Spurenelement-Analysen sowie ^{230}Th -Altersbestimmungen durchgeführt. Diese wurden mit Dünnschliffanalysen der Petrologie kombiniert. Wo möglich, führten wir kontinuierliche und diskrete Messungen an den Probenahmestellen durch, um ein besseres Verständnis für das Höhlenklima zu erhalten.

Kapitel 2 und 3 beleuchten die Sensitivität von hochgelegenen Tropfsteinen auf Temperatur und Verfügbarkeit von Wasser, die beide durch interne und externe Klimavariationen beeinflusst werden. Der Tropfstein MF3 aus dem Schafloch erlaubt einzigartige Einblicke in die regionale Auswirkung von Klimavariabilität in Zentraleuropa im MIS 6 und MIS 7. Die Probe bildet die Struktur der vorletzten Vergletscherung der Alpen hochauflösend ab und bringt neue Erkenntnisse über die Art dieses wichtigen klimatischen Übergangs.

Kapitel 4 und 5 beschreiben die hochauflösenden $\delta^{18}\text{O}$ -Werte und elementare Zusammensetzung von Tropfsteinen aus der Milandre-Höhle, die das Spätglazial-Holozän abdecken. Ein detaillierter Vergleich mit Eisbohrkernen von Grönland und Sediment aus dem Gerzensee (Zentralschweiz) zeigt Ähnlichkeiten in Langzeit-Änderungen von atmosphärischen Zirkulationsmustern in der gesamten Region des Nordatlantiks nach der letzten Eiszeit. Im Gegensatz dazu ist die Signatur des $\delta^{18}\text{O}$ im Holozän unterschiedlich zu derjenigen Zentraleuropas. Dies ergibt wichtige Erkenntnisse zu regionalen Verbindungen und lokalen Reaktionen auf Temperaturänderungen, Niederschlagsvariabilität in Funktion der Jahreszeit und atmosphärischen Prozessen. Die Nutzung einer robusten $\delta^{18}\text{O}$ /Temperatur-Transferfunktion erlaubte die Erstellung einer hochaufgelösten Temperaturrekonstruktion der Herbst-Winter-Frühlingstemperaturen bei der Milandre.-Höhle innerhalb der letzten 14 550 Jahre.

Zusammenfassend zeigt die vorliegende Arbeit neue Resultate zur klimatischen Variabilität in der Schweiz in zwei Intervallen der letzten 230 000 Jahre. Sie postuliert grosse Fernverbindungen in der nördlichen Hemisphäre und betont die Rolle der Besonnung und Obliquität als wichtige klimabeeinflussende Faktoren. Die neuen hochauflösenden, genau datierten $\delta^{18}\text{O}$ -Zeitreihen und Wintertemperaturrekonstruktionen aus dem Jura in den letzten 14 550 a werden als repräsentativ für Zentraleuropa angesehen.

*“If we knew what it was we were doing,
it would not be called research, would it?”*

ALBERT EINSTEIN

CHAPTER 1.

INTRODUCTION

1.1. OBJECTIVES AND STRUCTURE OF THE THESIS

1.1.1. TASKS AND IMPORTANCE WITHIN THE STALCLIM PROJECT

This PhD thesis is part of the Sinergia STALCLIM project “STALCLIM - Multi-proxy climatic and environmental reconstructions from stalagmites from Switzerland, Turkey, Arabia and India”. The STALCLIM project includes disciplines of Physical, Chemical and Geological Sciences, involving six groups based at Bern University and ETH Zürich (Fig.1.1).

The goal of this sub-group (STALCLIM A) was to construct highly resolved and precisely dated paleoclimate records from stalagmites sampled in Swiss caves and provide new information regarding the paleoclimatic and paleoenvironmental variability in the region. This was achieved by using a broad array of analytical techniques (determine growth intervals, stable isotopes analysis, calcite petrology observation) and combining the information with a suite of temperature sensitive speleothem proxies (fluid inclusion stable isotopes, gas inclusions and trace elements) as well as paleo-precipitation proxies (trace elements, water content). This PhD thesis is an integral part of STALCLIM having sampled and tested the quality of newly collected stalagmites. Through this work, the group has obtained established chronologies, initial geochemical data sets ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) and first environmental interpretations, used to decide and coordinate the analysis strategy for the other sub-groups. With the exception of laboratory and coordination tasks, STALCLIM A was responsible for the organization of field trips, not only for sampling campaigns but equally to monitor present-day conditions in the selected caves, which is a key-aspect for the calibration of multiple speleothem proxies.

Figure 1.1. Organization and tasks within the STALCLIM project. This study is the contribution of the STALCLIM_A group

1.1.2. STRUCTURE OF THIS THESIS

This thesis, *Late Quaternary and Holocene paleoclimate and paleoenvironmental reconstruction – a multi-proxy approach on Swiss speleothems*, comprises six chapters, with each chapter comprising its own reference list. Chapter 1 provides a general introduction to the thesis topic, the study area and the applied methodologies. Chapters 2 to 5 represent four individual manuscripts, either submitted or in preparation, for publication in peer-reviewed scientific journals. Chapter 6 presents an overall conclusion of the thesis and provides an outlook for future research in this field.

These four manuscripts represent the major tasks that contribute to this PhD thesis, and can be summarized as follows:

- Chapter 2: *Alpine climate variability during MIS 7 and MIS 6 as recorded in growth intervals of a stalagmite from Alpstein Mts. (Swiss Alps)* investigates the MF3 speleothem growth in Schafslösch Cave (Alpstein Mts., Appenzell), based on precise dating, petrography, stable isotopes, organic matter and trace elements content. Intervals of calcite formation are described with regard to regional geomorphological and environmental (at the surface and in cave) settings. Furthermore, information regarding internal and external climate factors that induced interstadial and interglacial conditions in this high alpine area is presented, together with a novel indication of glacier dynamics in the region during the penultimate glaciation.

- Chapter 3: *Timing and nature of the penultimate deglaciation in a high alpine stalagmite from Switzerland*; *detailed study of the structure and triggers of penultimate deglaciation as recorded in speleothem MF3 (Alpstein Mts., Appenzell)*. This chapter provides the first highly- resolved isotopic-age profile for the penultimate deglaciation from the northern fringe of the Alps. Petrography, ultra-high stable isotopes and trace element analysis highlight the importance of internal and external climate triggers responsible for deglaciations in high alpine areas, and display a regional and hemispheric teleconnection over this interval.

- Chapter 4: *Lateglacial environmental and temperature reconstruction in Central Europe: a multi-proxy and multi-techniques approach on speleothems from Milandre Cave (Swiss Jura Mountains)*, presents Lateglacial high-resolution quantitative and qualitative paleoclimate reconstructions in Central Europe based on stable isotopes and trace elements from three coeval speleothems from Milandre Cave (Swiss Jura Mountains). A new temperature transfer function was developed based on three independent lines of evidence.

- Chapter 5: *Preliminary results on Holocene cold temperature reconstructions, as recorded in speleothem M6 (Milandre Cave, Swiss Jura Mountains)*, presents highly-resolved and precise Holocene $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ records from sample M6 (Milandre Cave, Swiss Jura Mts.) and the first results of cold-season temperature reconstructions at the site. An extensive analysing and dating campaign aimed to establish precise chronologies and high resolution long-term climate variability at the cave site, with results which are representative for the Central European region.

1.2. GENERAL SETTING AND PREVIOUS SPELEOTHEM STUDIES IN SWITZERLAND

Climatologically, the northern side of the Swiss Alps and Jura Mountains shows a temperate climate with a considerable Atlantic influence. The Alpine chain and Jura Mountains are located on the southern fringe of the extra-tropical westerlies and form an orographic border between the Mediterranean and the North Atlantic climatic zones (Sodemann and Zubler, 2010). The climate is strongly tied to processes over the North Atlantic Ocean and its sea-ice system, making this region very suitable for the study of climatic and atmospheric processes over the North Atlantic region (Wanner et al., 1997). Cave speleothems offer an advantage, when compared to other natural archives, in recording regional to hemispheric scale climate processes due to their i) high resolution stratigraphy (up to seasonal scale), ii) high preservation potential over long time intervals, iii) high resistance to post depositional processes that may alter their proxy quality (Turgon and Lundberg, 2007).

Almost 20 % of the surface of Switzerland is represented by karst areas which host more than 9000 caves, including two of the most extensive cave systems in the world (Hölloch and Siebenhengste cave system). Distribution of the caves, both in areas that were glaciated or ice-free during the Quaternary history of Switzerland (Fig. 1.2), allows the unique potential to improve our knowledge with regard to the presence and/or dynamics of glaciers over long time intervals (e.g. Spötl et al., 2007).

Figure 1.2. Swiss caves distribution (dots, data from *SISKA* and *Atlas der Schweiz 2.0*) and spatial extension of glaciers during the Last Glacial Maximum interval in Switzerland (blue color, data from *map.geo.admin.ch*).

Until now, speleothems from the Swiss caves were primarily used to reconstruct growing intervals, cave evolution, geomorphologic surface evolution (e.g. valley incision) and seismic and neotectonic events (please refer to Fig. 1.3). More recently however, new high resolution analyses of the calcite isotopic composition of samples has been published for Swiss speleothems (Luetscher et al., 2011, 2015; Boch et al., 2011).

Figure 1.3. Karst areas in Switzerland (blue, data from *SISKA* and *Atlas der Schweiz 2.0*) and previous studies of speleothems from Swiss caves (modified from Häuselmann et al., 2013).

1.3. SPELEOTHEMS AS CLIMATE AND ENVIRONMENTAL ARCHIVES

1.3.1. SPELEOTHEM FORMATION

Speleothems are secondary carbonate deposits found in natural caves (large scale solution cavities) or artificial (man-made) tunnels. Among calcium carbonate minerals commonly found in caves (calcite, aragonite, vaterite, huntite, magnesite and dolomite, Hill and Forti, 1997), calcite is the most abundant due to its stable form under the physical conditions (temperature, total pressure and partial P_{CO_2}) found in the cave environment (White, 2007).

The mechanisms of speleothem formation are simple (see review in Fairchild et al., 2006). Three main stages characterize their deposition, as summarized in the reactions listed below (Roques, 1962):

Carbonic acid is produced as a result of meteoric water mixing with additional soil CO_2 (produced as a result of decaying organic matter, microbial processes and plants root respiration. Meteoric water has a P_{CO_2} of $10^{-3.5}$ bar (White, 2007), as the absorption of additional CO_2 during its percolation downward in the soil column brings it into equilibrium with the P_{CO_2} in the soil, reaching a P_{CO_2} of 10^{-1} bar (White, 2007). The dissolution capacity of the resulting solution is increased and becomes undersaturated with respect to CaCO_3 (“aggressive water”, Ford and Williams, 1989). During its percolation through the pores and fractures of the carbonatic rock, this weak carbonic acid reacts with CaCO_3 and will produce a calcium bicarbonate solution. The solution will continue to dissolve CaCO_3 and hold more Ca^{2+} ions until saturation is reached. As higher P_{CO_2} levels are produced in the soils, higher concentrations of Ca^{2+} will be required for the solution to reach saturation. As the saturated solution reaches the cave gallery, in the form of saturated CaCO_3 -bearing drip waters, CO_2 degasses as it is out of equilibrium with that of the cave atmosphere which has a lower P_{CO_2} (around $10^{-2.5}$ bar, White, 2007). As a result of degassing, the solution becomes supersaturated with respect to calcite and as a result carbonate minerals precipitate out of solution, forming different speleothem formations in the spelean environment. Most caves have high humidity, typically 95-100% (Tanner, 2010), minimizing the evaporation of drip water (Hendy, 1971). Therefore CO_2 degassing and not evaporation will be the dominant factor in calcite precipitation (McDermott, 2004). Speleothems can also form without the presence of soil and vegetation above the cave. If pyrite is present in the host rock and under oxidizing condition, sulfuric acid forms and dissolves the host rock and produce excess CO_2 (Atkinson, 1983). It has been also suggested that warming up of water while percolating through the host rock or entering the cave, or by dissolving Ca-bearing minerals (“common-ion effect”) can cause calcite supersaturation and calcite may subsequently precipitate in the caves (Dreybrodt, 1982; Atkinson, 1983).

1.3.2. GEOCHEMISTRY OF SPELEOTHEMS

The climatic and environmental changes at the surface are transmitted to the cave through the chemical and physical properties of the drip water, and preserved in the speleothem calcite. In order to reconstruct these changes, this study combined information from the following speleothem proxies: growth intervals and growth rates, petrography of the calcite, calcite stable isotopes (oxygen and carbon), trace elements and organic matter concentration in calcite (Fig. 1.4, Frisia and Borsato, 2010).

Figure 1.4. Transfer of climate proxies in the speleothem calcite (Frisia and Borsato, 2010)

1.3.2.1. U-SERIES DATING

The Uranium disequilibrium dating method is widely used in dating speleothems. Isotopes of uranium leached from the bedrock are co-precipitated in the calcite structure as uranyl carbonate ($\text{UO}_2(\text{CO}_3)_x$). The ^{238}U ($t_{0.5}=4.47$ Ga) decay chain begins with an alpha decay to ^{234}Th ($t_{0.5}=24.1$ days), which will be followed by a decay to ^{234}Pa ($t_{0.5}=6.69$ hours), ^{234}U ($t_{0.5}=245$ ka), ^{230}Th ($t_{0.5}=75$ ka), ^{226}Ra ($t_{0.5}=1.6$ ka), followed by a number of short-lived nuclides until it reaches the stable ^{206}Pb (Richards and Dorale, 2003). Ages are calculated based on measurements of $^{230}\text{Th}/^{234}\text{U}$ and $^{234}\text{U}/^{238}\text{U}$ in speleothem calcite (Fig. 1.5), which is considered to initially be deficient in thorium, as thorium is essentially insoluble and not transported by the parent water in the cave environment. An indication of detrital contamination in the sample is given by the presence of ^{232}Th in the Th spectrum. ^{232}Th is a non-radiogenic isotope that only occurs in water as a trace impurity. Nevertheless, the $^{230}\text{Th}/^{232}\text{Th}$ ratio can be used as a basis to correct the ages for detrital contamination (Richards and Dorale, 2003). Special attention should be given to samples where a $^{230}\text{Th}/^{232}\text{Th}$ activity ratio < 200 is measured (Richards and Dorale, 2003). The isochron methodology (measuring coeval subsamples of calcite) can be used to control both the detrital contamination and for any petrographic indications of “open system” activity in the sample (e.g. recrystallization of calcite, mobilization of nuclides, Schwarcz, 1989; Richards and Dorale, 2003).

A sub-sampling strategy for age determination should include: i) measurement of overview samples to determine the age range of the sample and its uranium concentration, ii) avoidance of dirty (detrital contaminated) and hiatuses sections, recrystallized and open pores areas of the sample. Detrital contamination of the sample and remobilization of uranium lead to older ages than the real age, while mobilization of fresh drip water within older speleothem layers (via pores) and precipitation of fresh calcite in pores results in younger ages.

Figure 1.5. Nuclides of U-decay chain used to calculate calcite ^{230}Th ages

Important advances have been made both in accurately constraining the decay constants and in measuring of daughter-to-parent nuclide ratio (Cheng et al., 2013). The method provides precise ^{230}Th ages for calcite precipitated in the last 500 ka (e.g. Cheng et al., 2009, 2012; Badertscher et al., 2011), limited by the secular equilibrium conditions caused by the decay rate of ^{230}Th .

1.3.2.2. PETROGRAPHY OF THE CALCITE

Variations in calcite crystals fabrics are mostly related to variations in drip rates and departures from equilibrium growth (high-supersaturation levels of the cave drip water, Frisia et al., 2000). Columnar and microcrystalline fabrics form in low-supersaturation conditions (quasi-equilibrium conditions), whereas dendritic fabrics form in disequilibrium conditions as a result of low and irregular drip rates (prolonged outgassing, Frisia et al., 2000). The dense close columnar fabric is suggested to be formed at low supersaturation and regular flow conditions, with negligible presence of impurities (Frisia et al., 2000). Open columnar fabric could form during faster growth rates, high supersaturation conditions, presence of impurities and high discharge variability (Frisia and Borsato, 2010; Boch et al., 2011).

1.3.2.3. STABLE ISOTOPES IN SPELEOTHEM CALCITE

Stable isotopes are atoms of the same element exhibiting different atomic masses. The natural abundance of oxygen (O) stable isotopes is: ^{16}O (99.763 %), ^{17}O (0.0375 %) and ^{18}O (0.1995 %), and of carbon (C) stable isotopes: ^{12}C (98.89 %) and ^{13}C (1.11 %).

The stable isotopic composition of oxygen and carbon are not measured in absolute terms, but are reported as enrichments and depletions relative to a standard of known composition. Isotopic composition is usually reported against the Vienna PeeDee Belemnite (VPDB) standard for calcite samples and Vienna Standard Mean Ocean Water (VSMOW) standard for water samples, using the δ notation and following equation:

$$\delta^{18}\text{O}_{\text{sample}} (\text{‰}) = \left[\left(\frac{^{18}\text{O}}{^{16}\text{O}} \right)_{\text{sample}} - \left(\frac{^{18}\text{O}}{^{16}\text{O}} \right)_{\text{standard}} \right] * 1000 / \left(\frac{^{18}\text{O}}{^{16}\text{O}} \right)_{\text{standard}}$$

$$\delta^{13}\text{C}_{\text{sample}} (\text{‰}) = \left[\left(\frac{^{14}\text{C}}{^{13}\text{C}} \right)_{\text{sample}} - \left(\frac{^{14}\text{C}}{^{13}\text{C}} \right)_{\text{standard}} \right] * 1000 / \left(\frac{^{14}\text{C}}{^{13}\text{C}} \right)_{\text{standard}}$$

If the $\delta^{18}\text{O}$ values are more negative, the term ^{18}O depleted or ^{16}O enriched are used. Conversely, if the $\delta^{18}\text{O}$ values are more positive, these are referred to as ^{18}O enriched or ^{16}O depleted.

The $\delta^{18}\text{O}_{\text{precipitation}}$ decreases with increasing latitude, altitude, distance from coast, increasing rainfall

(tropics) and with a drop in temperature (mid-latitudes, Fig. 1.6). In mid-latitude regions, the season of precipitation recharge of the karst aquifer is during winter to spring seasons, with infiltration during summer less likely to infiltrate due to higher evapotranspiration rates (Genty et al., 2006).

Under favorable conditions (calcite is deposited in conditions close to equilibrium) $\delta^{18}\text{O}$ of speleothems will be dominated by the i) $\delta^{18}\text{O}$ signature of precipitation above the cave and ii) isotopic fractionation occurring during the calcite precipitation (controlled by the temperature at the moment of calcite precipitation). As widely discussed in literature, variations in $\delta^{18}\text{O}$ of precipitation and drip water depend on several factors such as i) changes in the source of the moisture, ii) isotopic composition of the moisture (namely North Atlantic Ocean for our region of interest), iii) the “amount effect”, and iv) surface and cave air temperature. Excellent reviews on the subject were published by McDermott (2004), Fairchild et al. (2006) and Lachniet (2009). As well as this, local complex processes (in hydrologic cycle, soil, epikarst and cave environment) can influence the incorporation of oxygen isotopes, and consequently, the variability of $\delta^{18}\text{O}$ values in the stalagmite layers deposited at different times. To overcome the complexity of processes that can overprint the climatic signal in speleothems, it is highly recommended to analyze coeval speleothems from the same cave and/or region.

Fig. 1.6. Overview on the primary controls on variations in the $\delta^{18}\text{O}$ of precipitation and $\delta^{18}\text{O}$ of speleothem calcite (Lachniet, 2009).

The main influencing factors of calcite $\delta^{13}\text{C}$ include changes in i) the density and type of vegetation (proportion of C3 and C4 plants), ii) microbial processes in the soil zone, iii) recharge conditions (closed versus open system dissolution) and iv) CO_2 degassing. In general, $\delta^{13}\text{C}$ calcite values of -14 to -6‰ and -6 to +2‰ can be indicative of C3 and C4 vegetation respectively (McDermott, 2004; Frisia and Borsato, 2010). Recharge conditions and equilibration of infiltrating water with soil CO_2 (closed versus open system dissolution) can be an additional parameter determining $\delta^{13}\text{C}$ values in speleothems, particularly when soils are thin or absent. Finally, low drip rates and enhanced CO_2 degassing during calcite precipitation and ventilation can lead to elevated calcite $\delta^{13}\text{C}$ values (Baker et al., 1997, 2011; Mühlinghaus et al., 2009, Deininger et al., 2012). Spötl et al., (2005) and references therein, stressed about the importance of air circulation in dynamically ventilated caves, which may result in an enhanced carbon kinetic fractionation factor.

1.3.2.4. TRACE ELEMENTS AND ORGANIC MATTER CONCENTRATION

Trace elements are transported as particles, solutes or adsorbed onto colloids, and incorporated into speleothem calcite according to their concentration in drip water (Fairchild and Treble, 2009). They are incorporated within the calcite crystal lattice by substitution of a major ion, at defect sides, or as colloids and detrital particles (Fairchild and Treble, 2009). Their concentrations provide additional information on recharge conditions, groundwater residence time, soil conditions, and help reduce uncertainties associated with the interpretation of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ (Fairchild and Baker, 2012, Fig. 1.7).

Elements such as Mg, Sr, U and Ba are well-established indicators for effective rainfall and groundwater residence time in the karst aquifer above the cave (Fairchild and McMillan, 2007; McDonald et al., 2004; Roberts et al., 1998; Zhou et al., 2005). In addition, Mg and U contents are also related to prior calcite precipitation at times of low effective moisture (Fairchild and McMillan, 2007; Drysdale et al., 2009) and rock weathering (Ayalon et al., 1999).

Along with $\delta^{13}\text{C}$, P concentration is used as an indicator for soil activity and vegetation (Borsato et al., 2007; Fairchild et al., 2001; Treble et al., 2003). Rare earth elements such as Y and Ti are indicators for enhanced weathering of the overlying soil layer and the host rock (Richter et al., 2004; Zhou et al., 2008). Schimpf et al. (2011) used Y as a tracer for detrital (including colloidal) transport and used it as a proxy for rainfall. Ti is often used as a tracer for detritus, due to its extremely low solubility (Fairchild and Baker, 2012). Another element typically incorporated in the fine-grained detrital layers deposited on speleothems during flooding events is Al, which has been used as a paleohydrological indicator (Borsato et al., 2007).

Figure 1.7. Overview on trace element incorporation mechanisms into stalagmite structure (figure modified from Lascau and Feinberg, 2011), based on data from Fairchild et al. (2007), Fairchild and Treble (2009), Stoll et al. (2012), and Hartland et al. (2012). Please refer to the text for further details.

Organic matter is also incorporated as a trace component either between or within the mineral crystals (Ramseyer et al., 1997). Organic matter preserved in speleothems, detected as fluorescence intensity, is used to identify climate and hydrological-induced changes in the rate of organic matter turnover and its release into the groundwater system (Proctor et al., 2000, Linge et al., 2009).

1.4. METHODS

1.4.1. FIELD CAMPAIGNS AND CAVE PARAMETERS

For this study, we collected and/or received samples from the Jura Mountains and the northern side of the Swiss Alps. Actively growing stalagmites were collected from Milandre Cave, St. Beatus Cave, Grotte aux Fees du Vallorbe. Samples remobilized from their growing place were collected from Hobbit Cave, Haglättsch Cave, Chammfluhöhle, Romontberghöhle and Schafsloch Cave. The overview with growing intervals for each sample is presented in Table 1.1 and Fig. 1.8.

Figure 1.8. Karst areas in Switzerland (blue, *Atlas der Schweiz*) and cave locations of samples studied in the STALCLIM project (modified from Häuselmann et al., 2013)

Cave (region)	Alt. (m asl)	Sample	Type	Length (mm)	Growing interval
St. Beatus Cave (BE)	690	BHN_1	stalagmite	535	MIS 1
Hölloch (SZ)	740	Höll_A	soda straw	600	MIS 1
Schafsloch (AI)	1890	MF_3	stalagmite	210	MIS 5-7
Milandre Cave (NE)	400	M2	stalagmite	250	MIS 1
Milandre Cave (NE)	400	M6	stalagmite	1450	MIS 1
Milandre Cave (NE)	400	M8	stalagmite	135	MIS 1
Grotte aux Fees (VD)	895	GEF_1	stalagmite	695	MIS 1
Hobbit Cave (BE)	2000	Ho_1	stalagmite	210	MIS 5
Haglättsch Cave (BE)	1660	HAG_01	stalagmite	230	MIS 5
Weidhöhle bei EH (SZ)	780	WEH_1	core	300	MIS 2-3
Chammfluehöhle (BE)	650	CHAM_1	stalagmite	540	MIS 1
Romontberghöhle (BE)	1156	ROM_01	stalagmite	670	?

Table 1.1. Inventory of the Swiss samples collected/studied during the STALCLIM project (see Appendix for data)

The in-situ stalagmites were collected in deep parts of the cave (away from the entrance) where temperature is constant and equal to the multi-annual temperature average, with a high relative humidity (RH > 95%) and from cave passages protected from ventilation and/or close to underground rivers. A good understanding of the cave genesis and evolution is also important, in order to avoid areas frequently exposed to flooding in the past, or within the vicinity of a former entrance to the cave. We chose caves with galleries close to the surface, to minimize the buffering of the isotopic signal in the aquifer over long time intervals.

Before removing a stalagmite we have observed:

- the calcite texture and porosity of stalagmites in the gallery (ideally done on samples detached from their initial growing place, or drilling “reconnaissance cores” in the stalagmites, photo Fig. 8A).
- under certain circumstances (large diameter stalagmites or flowstone) a 30 cm long cores were drilled (Fig. 8B)
- the feeding point of the stalagmite (soda straws are preferred)
- the distance from stalagmite to the feeding point (at high distances the drip water will splash and more calcite will be deposited on the flanks of the sample)
- the shape and height of the sample (stalagmites with cylindrical growth geometry are favoured due to their faster growth rate and tendency to form in close isotopic equilibrium with the parental drip water).

To monitor present day conditions at the Milandre sampling site, the following equipment was installed: a STALAGMATE drip logger (Stalagmate Plus Mk2b, Driptych, UK, Matthey and Collister, 2008); a temperature logger (UTL-3 Scientific Dataloggers, GEOTEST, Zollikofen and Snow and Avalanche Research SFL, Davos) and glass watches in order to precipitate fresh calcite. Relative humidity was measured over time using an Aspirationspsychrometer Hänni device (Jegensdorf, CH). P_{CO_2} was measured using a Dräger X-am 5600 device, and air flow speed measured with a Dräger X-am 5600.

1.4.2. LABORATORY ANALYSIS

For Uranium-series dating (^{230}Th hereinafter), approximately 200 mg of powder was drilled along discrete growth horizons. Overview age determination was performed at the Institute for Geological Sciences, University of Bern, Switzerland, with a detailed description of the method available in Fleitmann et al. (2007). Isotope analysis was conducted using a Nu Instruments MC-ICP-MS at the Institute for Geological Sciences, University of Bern.

Most of ^{230}Th analysis were performed in the laboratory of Dr. L. Edwards at the Department of Earth Sciences, University of Minnesota, and are kindly provided for this thesis. Element separation was done using the procedure of Edwards et al. (1987). The ^{230}Th ages were determined on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS, Thermo-Finnigan Neptune) at the Department of Earth Sciences, University of Minnesota. Details of the methods, including standards used for mass fractionation and yield correction can be found in Cheng et al. (2013).

In order to construct stalagmite age models the calculated ages were plotted versus their distance from the top of the stalagmite. Linear interpolation was applied where only two ages were available between two hiatuses in the sample, and statistical age models (StalAge, Scholz and Hoffmann, 2011; COPRA, Breitenbach et al., 2012) were used where more ages were available. We stress the importance of providing as many ages as possible for each sample, in order to correctly assess the presence of hiatuses and changes in the growth rate of the samples.

Calcite stable isotope ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) measurements were performed in the laboratory of the Institute for Geological Sciences, University of Bern. Calcite powder was micromilled continuously, using an electronically controlled micromill equipped with a 0.5 mm diameter drilled head. About 150-200 μg of powdered sample was placed in 12 ml vacutainers, flushed with He, and reacted with 5 drops of 99 % P_2O_5 at 70°C for 80 minutes. The samples were measured using a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. The analytical reproducibility based on repeated measurement of the internal standard for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ is lower than 0.07 and 0.06 ‰ VPDB (1 σ).

Methods development and raw-data analyses of calcite trace elements and fluid inclusions were performed by the other groups of the STALCLIM project, and were kindly provided for use in this thesis, in order to construct age models, compare results and/or provide a climatological and environmental data interpretation. Determination of minor and major trace element concentration in the samples, using a laser ablation technique, was performed in the Department of Chemistry and Applied Biosciences, Laboratory of Inorganic Chemistry, ETH Zürich. We used a 193 nm ArF excimer laser (GeoLas Pro, Lambda Physik) coupled to a quadrupole ICP-MS (ELAN 6100 DRC+, Perkin Elmer). A detailed description of the experimental setup is given in Kovacs et al. (2010) and optimized as described in Tabersky et al. (2013). The method is nondestructive, does not require an ablation cell, and analyses can be performed at a speed of 1.2 cm/min. Noble gases in fluid inclusions (NG) were measured at the Department of Water Resources and Drinking Water, Eawag, using a recently developed combined vacuum crushing and sieving (CVCS) system'. The setup and operation conditions are described in Vogel et al. (2013). $\delta^{18}\text{O}$ and δD of speleothem fluid inclusions were measured using a wavelength scanned cavity ring down spectroscopy (WS-CRDS) instrument, following the set up and procedure described in Affolter et al. (2014).

2.1. INTRODUCTION

Temperature is the key factor controlling landscape evolution and vegetation development in alpine areas (Meyer et al., 2012). It has been shown that speleothems from high alpine caves are one of the rare climate archives that can provide long and continuous records of temperature changes over several glacial and interglacial cycles (Spötl and Mangini, 2010; Luetscher et al., 2015 and references therein). Although many factors may contribute to speleothem deposition, there are two dominant conditions that must be met: i) elevated CO₂ levels above atmospheric values must be generated (generally in the soil zone), and ii) water must be available for recharge (Fairchild and Baker, 2012 and references therein). Both are highly dependent on the climate at the cave site and therefore, major depositional hiatuses represent significant spatial and temporal shifts in environmental and/or climatic conditions in the region (Spötl et al., 2008). More importantly, the timing and the duration of these hiatuses can be precisely characterized within speleothems.

If, during glacial intervals, a glacier body is present at the cave surface, changes in its state from cold- to warm - based glacier is reflected as a new calcite generation, and provides evidence of the relationship of alpine glaciers responds to internal and external climate triggers. To date, the classical approach is to correlate Quaternary Alpine stratigraphy (along with phases of glaciers advance and retreat) with low-latitude and low-altitude oxygen isotope records (e.g. marine sediment records, mainly proxy for global ice volume, Preusser et al., 2011). Independently dated records from this region are essential for our understanding of local and regional geomorphologic and climatic evolution, and will also enable a meaningful correlation of events between different environments and sites.

In the Alpine region, Marine Isotopic Stages (MIS) 7 and 6 are a major topic of scientific interest due to the rare high resolution records covering this time interval (Spötl et al., 2008, Preusser et al., 2005). The goal of this work is to document climatic variability during both these stages by applying a multi-proxy approach on a stalagmite collected from the high alpine Schafslösch Cave. The information preserved in stalagmite MF3 will aid in expanding our knowledge of the environmental and climatic conditions in the region between 130 to 230 ka BP. This new independently-dated terrestrial record can provide further insights into the response of alpine climate and glacier dynamics, with respect to external and internal climate forcing, as well as its regional and hemispheric connections.

2.2. SITE AND SAMPLE DESCRIPTION

Schafslösch Cave is located in the Appenzell Alps (47°14'N, 9°23'E, 1890 masl), a mountain range slightly detached from the main alpine body (Fig. 2.1A). The northern Alpine climate is strongly influenced by processes over the Atlantic Ocean and its sea-ice system (Wanner et al., 1997). The Alps are located on the southern side of the extra-tropical westerlies, acting as a border between the Mediterranean and the North Atlantic climatic zones. Climatically, the region has a negligible Mediterranean influence (Sodemann and Zubler, 2009), with moisture sourced in the Mediterranean region accounting for a maximum of 20% of the total moisture budget mainly during the winter months. Mean annual air temperature (MAAT) and precipitation rate between 1961 and 1990 measured at Säntis meteorological station (47°24'N, 9°34'E, 2500 masl) is 2.6 °C and 2200 mm/year, respectively (Fig. 2.1B). In these high alpine conditions, average temperature of the warm months (April to September) is 5.8 °C, and of the cold months (October to March) is -1.0 °C, allowing the presence of snow until late spring. The area is karstified, with alpine grassland and a soil depth of only several centimeters.

Figure 2.1. *A. Location of the Schafsloch Cave and the other sites mentioned in the text; B. Meteorological parameters measured at Sântis meteorological station (near Schafsloch Cave); C. View of the Alpstein Mountains and its surface geological formations; D. Garshella Formation outcropping close to the cave site; E. Seewerkalk profile at the entrance of Schafsloch Cave (indicated by the arrow) F. Map of Schafsloch Cave (plan and profile). Red dot indicates the location of the sediment pile where MF3 sample was found remobilized.*

Geologically the Alpstein is formed by a folded succession of Cretaceous sedimentary rocks. Schratten Kalk (Cenomanian-Santonian) is the dominating geological formation in Alpstein, a massive platform light-color carbonate, very rich in fossils. Seewer Kalk (early Barremian-early Aptian) is a well stratified pelagic limestone, with interbedded clay layers. Between Seewer Kalk and Schratten Kalk formations lies the glauconitic sandy-limestone formation of Garschella Formation (Geologischer Atlas der Schweiz, 1982). The steep carbonate relief was modeled and eroded during the last glacial cycle (Marine Isotope Stage 2, MIS 2), when ice reached an elevation of about 2000 m at the study site. Although MIS 6 is considered far more extensive compared to the Last Glaciation (Ehlers et al., 2011), the presence of a glacier during the penultimate glacial was not so far been documented at the site (Preusser et al., 2011).

The accessible part of Schafsloch Cave presently developed in the Seewer Kalk formation, and the bedrock above the cave is formed exclusively by this type of rock. Garschella Formation outcrops several tens of meters from the cave entrance (Fig. 2.1C-E). Schafsloch Cave developed 20 m below the surface, and the total length of the cave is not known, as after 25 m the access is blocked by a 2 m pile of sediments (Fig. 2.1F). Temperature measurement 25 m from the cave entrance was 6.5 °C in September 2011. This temperature is considerably higher than the temperature expected in the (unexplored) deeper galleries, as mean annual temperature at the site is 2.6°C and the temperature in Swiss caves located at similar altitudes ranges between 2.5 - 4.0 °C (Luetscher et al., 2011, 2015). Conditions in the cave are almost dry, and no actively growing speleothems are present. Similar conditions are reported in other caves of this area (M. Fisher, pers. comm.) although the large number of inactive speleothems (some of them older than 500 ka) indicates that deposition was more intensive in the past.

Sample MF3, subject of this study, was recovered from the upper part of the sediment pile, therefore remobilized from its original growth place. The transport distance was short, as proved by the small surface alteration of the sample. Transport direction of the sample, shown by the pebbles imbrication in the sediment pile and scallops on the cave wall, was toward the cave entrance. Stalagmite MF3 is 215 mm along the vertical growth axis, with a basal diameter of 80 mm (Fig. 2.2). It is composed of dense and translucent columnar-fibrous calcite. Localized dissolution porosity and recrystallization is observed between 79 - 100 mm depth in the sample. No macroscopic banding is observed.

2.3. ANALITICAL METHODES

The stalagmite was cut longitudinally and polished. The top 80 mm of the sample were studied petrographically in thin sections by using an optical transmission microscope (standard transparent and UV light). The fabric of calcite and its organic matter content will help to better understand the environmental and cave conditions in which the sample formed. More importantly, an effort was made to document the presence and lateral extent of discontinuous petrographic boundaries (potential growth interruption) in the sample.

The stalagmite was dated using the $^{230}\text{Th}/^{234}\text{U}$ disequilibrium method. Age determination was performed on 70-100 mg calcite powder drilled along particular growth horizons in the sample. The chemical procedures of Edwards et al. (1987) were used for U/Th separation and isotopic analysis was performed on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS, Thermo-Finnigan-Neptune) at the Department of Earth Sciences, University of Minnesota. Details of the analytical procedure and U-series activity ratios are reported in Cheng et al. (2013). The U-series

Figure 2.2. *A.* Polished section of MF3 showing micromilling paths (white lines) for isotopic analysis, sampling locations for U/Th calcite dating (white dots) and dating results; *B.* Age-depth plot of the sample MF3 (dating results as solid circles with errors); *C.* Growing intervals identified in sample MF3 and paths location for trace elements analysis (TE I and TE II).

dating results are summarized in Table 2.1. Ages are reported as thousand years (ka) before AD1950. All ages are in chronological order within analytical errors. The analytical 2σ error is in the range of 0.3 to 1.0 %, due to low detrital contamination and high ^{238}U content of the sample (783 to 9855 ppb).

For stable isotope analysis a total of 735 samples were micromilled continuously using a 0.8 mm diameter drill, following the growth axis of the sample (Fig. 2.2A). The sampling resolution varies between 0.1 and 0.5 mm. Modern calcite was sampled from the top of a stalactite, collected in the nearby Alpeel Cave (Alpstein Mts., 45 m length, 1774 m asl). Oxygen and carbon isotopic analysis ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) were performed on a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. All $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values are calibrated and reported relative to the Vienna Pee Dee Belemnite (VPDB) standard. Analytical errors for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ are 0.07 ‰, respectively 0.06 ‰ VPDB (1σ).

Trace element analyses were carried out continuously at a resolution of 13 μm between 17.0–58.3 mm and 151.0 – 152.0 mm from the top of the sample by using a 193 nm ArF excimer laser (GeoLas Pro, Lambda Physik) coupled to a quadrupole ICP-MS (ELAN 6100 DRC+, Perkin Elmer). A detailed description of the experimental setup has already been given in Kovacs et al. (2010) and optimized as described in Tabersky et al. (2013). Two cleaning line scans were applied to remove potential contaminations on the sample surface and only one third was used for quantification. NIST SRM 610 was used as external standard and values were normalized to 100% sum of oxides. Data evaluation was carried out in STALQUANT, an in-house Python-based software program to reduce large amounts of point-by-point quantification data (Fricker, 2012).

2.4. RESULTS

2.4.1. GROWTH INTERVALS IN MF3 SAMPLE

It is common for high alpine stalagmites to present multiple growth-discontinuities, as their growth is very sensible to climatic and environmental changes above the cave (Spötl et al., 2007; Holzkämper et al., 2005).

Major discontinuities are associated with major environmental changes above the cave, although processes related to the cave environment and epikarst could account for minor discontinuities (rerouting of groundwater flow, blocking of the fissure feeding the stalagmite with drip water, temporarily submerging or burring of the sample (Spötl et al., 2007). Based on 30 ^{230}Th ages and petrographic observations, a robust age model was built for MF3 sample. Seven major hiatuses were identified in the sample, at 20.5, 33.75, 44.5, 49.0, 59.5, 71.0, 77.5, 214.5 mm depth. Macroscopic, under UV light, the hiatuses at 20.5, 77.5, and 214.5 cm depth show a distinctive intensity in photoluminescence.

Eight growth intervals were identified, and numbered from I to VIII in Fig. 2.3. The location of hiatuses is marked by gray lines, and other potential hiatuses at 49 and 137 mm depth (later discussed), are marked by gray dashed lines. Growth interval IV (GI_{IV}) was divided in two sub-intervals, noted GI_{IVa} and GI_{IVb} , as discussed later. Note that during GI_{IV} calcite precipitation was much more localized compared to the other GI, calcite built mainly laterally with respect to main the growth axis of the sample.

For each growth interval (GI) an age model was constructed. The StalAge algorithm (Scholz and Hoffmann, 2011) was used for GI_{I} , GI_{II} and GI_{VIII} , and linear interpolation between central ages for GI_{III} , GI_{IV} and GI_{V} . Special consideration must be given when referring to GI_{IVa} , GI_{VI} and GI_{VIII} . In GI_{VI} , please

note that in the case of an age reversal between two similar ages, we used the most precise age and an average growth rate of 0.01 mm/year (averaging growth rates calculated for GI_V and GI_{VII}). This approach was also used for GI_{VIII} , where only one age was available. Although we observed the presence of a corrosive surface at 49.25 mm depth (just above G_{IV}), the temporal extension of a series of irregular detrital-rich laminae overlying this corrosive surface between 44.25 and 49.25 mm (just below G_{III}) could not be determined. This interval was integrated in the age model as part of the growth interval GI_{IV} , and referred to as GI_{IVa} .

The age-depth model for MF3 is shown in Fig. 2.3, and a summary for each growth interval is presented in Table 2.3. As expected for an alpine sample, average growth rate is very slow, around 6 mm/ka for the entire sample, with a minimal growth rate during GI_{III} (1.1 mm/ka) and a maximum during GI_I (6.3 mm/ka).

GI	Distance from top (mm)	Age interval (ka BP)	Mean error (ka)	Growth rate (mm/year)
I	0.00-20.50	130.05-131.90	0.43	0.0902
II	20.6-33.75	133.05-137.39	0.54	0.0032
III	34.00-44.50	151.91-161.22	1.05	0.0011
IVa	44.75-49.00	180.22-181.15	1.36	0.0048
IVb	49.25-59.5	181.20-183.28	1.37	0.0048
V	60.00-71.00	185.94-189.11	1.42	0.0050
VI	71.50-77.50	198.48-199.68	1.68	0.0050
VII	78.00-214.50	205.19-220.08	1.38	0.0163
VIII	215.00-221.5	224.48-225.78	2.28	0.0050

U decay constants: $\lambda_{238} = 1.55125 \times 10^{-10}$ (Jaffey et al., 1971) and $\lambda_{234} = 2.82206 \times 10^{-6}$ (Cheng et al., 2013). Th decay constant: $\lambda_{230} = 9.1705 \times 10^{-6}$ (Cheng et al., 2013).

* $\delta^{234}\text{U} = ([^{234}\text{U}/^{238}\text{U}]_{\text{activity}} - 1) \times 1000$. ** $\delta^{234}\text{U}_{\text{initial}}$ was calculated based on ^{230}Th age (T), i.e., $\delta^{234}\text{U}_{\text{initial}} = \delta^{234}\text{U}_{\text{measured}} \times e^{(\lambda_{234} \times T)}$.

Corrected ^{230}Th ages assume the initial $^{230}\text{Th}/^{232}\text{Th}$ atomic ratio of $4.4 \pm 2.2 \times 10^{-6}$. Those are the values for a material at secular equilibrium, with the bulk earth $^{232}\text{Th}/^{238}\text{U}$ value of 3.8. The errors are arbitrarily assumed to be 50%.

***B.P. stands for “Before Present” where the “Present” is defined as the year 1950 A.D.

Regarding the reliability of the ^{230}Th ages, large analytical errors can be ruled out, as age measurements were carried out over several dating campaigns, with consistent chrono-stratigraphic results. Furthermore, two overview samples were additionally prepared and measured in the laboratories of the Institute of Geological Sciences in Bern, with consistent results. That being said, based on the literature (e.g. Wainer et al., 2011 and references therein) most commonly reported possibilities for an “age alteration” are given by the U leaching from the sample (open-system behavior), and/or detrital contamination of the sample. Both possibilities will lead to an overestimation of the ^{230}Th ages. We observed no major variations within short intervals in the U concentration that could indicate leaching or contamination. Highest U concentration oscillations are observed during GI_{IVb} (5 to 15 mg/kg), and here no powder was sampled for age determination. Mean Th concentrations are consistent within all GI (between 0.28 and 0.33 mg/kg). Furthermore, in the areas of the stalagmite where calcite powder was collected for ^{230}Th dating analysis we observed no evidence of large (connected) pores to generate new percolation paths for water, to dissolve or even precipitate new calcite generation. Based on these observations, we conclude that no internal heterogeneities could support a potential “open-system” behavior with respect to U in our sample.

Speleothem deposition between 130.1 ± 0.4 to 131.9 ± 0.6 ka BP, 133.1 ± 0.7 to 137.4 ± 1.4 ka BP, 151.9 ± 1.2 to 161.2 ± 1.0 ka BP, 180.2 ± 1.3 to 183.3 ± 1.4 ka BP, 185.9 ± 1.6 to 189.1 ± 1.4 ka BP, 198.5 ± 1.7 to 199.7 ± 1.7 ka BP, 205.2 ± 1.2 to 220.1 ± 2.3 ka BP, 224.5 ± 2.3 to 225.8 ± 2.3 ka BP span intervals during the MIS 7, MIS 6 and transition into MIS 5 (known as Termination II, T-II). This provides a first-order indication of past climatic conditions, as minimum conditions for calcite to precipitate in caves are i) the presence of drip water and ii) a (seasonal) cave temperature above 0°C . In MF3 sample, calcite deposition after 137.4 ka BP (largely discussed in Chapter 3) and between 230-185 ka BP support evidences of calcite precipitation in European caves from high and low altitudes (Holzkämpfer et al., 2005 and references therein; Wainer et al., 2011). Between 185 -137.4 ka BP similar favorable conditions in caves from high altitudes are not reported in literature, largely as this time interval falls well within MIS 6 (based on SPECMAP timescale, Imbrie et al., 1984). It is difficult to reconcile with the idea of favorable conditions for calcite to precipitate (temperatures above freezing point, and therefore presence of liquid water) in this high altitude cave at a time of regional atmospheric cooling and glacier expansion. As most of the speleothems from low-altitude cave sites commonly show slow or no growth during cold climatic periods (Hodge et al, 2008), in the case of a high-altitude speleothem we could consider the presence of a glacier above Schafslösch Cave, allowing a (slow) calcite precipitation during glacial and severe cold climate conditions (stadials). The presence of a warm based glacier can maintain the cave temperature above freezing point and provide water, although climatic conditions above the cave are below the freezing point. Similar settings are extensively described for calcite precipitation in Spannagel and Castleguard Caves (Atkinson 1983, Spötl et al., 2007). A warm-based glacier of 30 m thickness will offer thermal protection and keep host rock, and therefore cave temperature, above freezing point, contrasting with atmospheric temperatures reaching down to -8°C (Spötl and Mangini, 2008). Following this line of evidences, rather than claiming ice-free conditions above the cave during MIS 6, we propose that calcite formed as a direct result of a warm-based glacier presence above our cave (Fig. 2.4). Its basal meltwater would feed the karst aquifer, and allow a slow formation of calcite in the cave. The lack of carbon derived from soil can be replaced by: i) very slow precipitation as a result of warming of water after entering the cave or evaporation of drip water (Atkinson 1983 and references therein), or ii) oxidation of pyrite (Spötl et al., 2007) present in the geological succession from Alpstein Mountains.

We emphasize that formation of a new calcite generation in the cave during the times of glacier presence at the surface is related to changes in the glacier state (from cold- to warm-based), as a direct result of positive shifts in the warm season temperature at the surface.

Isotopic and trace element composition of the sample, as discussed below, allows further constraints of the processes that governed the formation of MF3 during individual growth intervals.

Figure 2.4. Sketch presenting favorable and unfavorable conditions for calcite to precipitate in a high alpine environment

2.4.2. OXYGEN AND CARBON ISOTOPE RECORDS

2.4.2.1. DISEQUILIBRIUM ISOTOPIC FRACTIONATION AND “SOURCE EFFECT”

CORRECTION

The isotopic signals could be affected by disequilibrium isotopes fractionation. The main controlling mechanisms are linked to changes in i) prior-calcite precipitation in the epikarst (directly related with changes in the length of flow path, CO₂ degassing, low water availability (Spötl et al., 2005; Matthey et al., 2010; Wiedner et al., 2008; Polag et al., 2010; Scholtz et al., 2009) and ii) rapid CO₂ degassing and calcite precipitation at the stalagmite surface (Baker et al., 1997; Daeron et al., 2011, Mickler et al., 2004). As our sample lacks macroscopic lamination, this prevented a signal reliability test using the classical Hendy test method (Hendy, 1971). As a strong correlation between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ could well indicate kinetic effects in the vadose zone and/or surface of the sample, r^2 was calculated for each GI, as presented in Fig. 2.5. Cross plotting of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of stalagmite MF3 exhibit overall a medium correlation ($r^2=0.39$, with a slope of -0.25). However, correlation of individual GI within the stalagmite vary from virtually absent ($r^2=0.01$) during GI_{IV} and GI_{VIII} to high ($r^2=0.64$) in the GI_{II} and GI_{III}. This could indicate a deterioration of the isotopic signal reliability in the latter ones. Nevertheless, if we compare the $\delta^{18}\text{O}$ from MF3, both during intervals of weak and strong kinetic control (e.g. GI_I, GI_{II}, GI_{VI} and GI_{VII}) with isotopic data from coeval samples collected from Spannagel and/or Corchia Cave (Spötl et al., 2007; Drysdale et al., 2009; Couchoud et al., 2011) we observe similar isotopic patterns, which give us confidence that the isotopic signal in MF3 is a reliable proxy.

$\delta^{18}\text{O}$ of alpine speleothems is primarily controlled by variations in $\delta^{18}\text{O}$ of drip water and therefore surface precipitation, whereas $\delta^{18}\text{O}$ of precipitation is related to source area of the moisture and local air temperature, global ice volume effect, seasonality of rainfall etc. In order to better compare the effect of

Figure 2.4. Correlation plot of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ in sample MF3 during different growth intervals

local changes in the $\delta^{18}\text{O}$ signal (e.g. air temperature during individual growth episodes, changes in the water source) we corrected the measured $\delta^{18}\text{O}$ for isotopic variations in the moisture source area (North Atlantic Ocean at our cave site). Between 230 and 130 ka BP, episodes of ice cap growth and melt down accounted for changes in relative sea level (RSL) ranging from -99 m to +13 m (Rohling et al., 2009). Therefore, changes in $\delta^{18}\text{O}$ of North Atlantic Ocean seawater will alone justify 0.3 to 0.8 ‰ VPDB variation in the MF3 $\delta^{18}\text{O}$ signal (we considered a change of 0.008 ± 0.002 ‰ VPDB per meter of sea level drop, Duplessy et al., 2007). This first order approximation uses the assumption that there was no major shift of the Atlantic vapor source compared to present. A summary of the mean $\delta^{18}\text{O}$ measured ($\delta^{18}\text{O}$), $\delta^{18}\text{O}$ correction applied and of the final corrected values ($\delta^{18}\text{O}_{\text{corr}}$) is presented in Table 2.4.

GI	MEAN

2.4.2.2. STABLE ISOTOPIC SIGNAL INTERPRETATION

The oxygen and carbon stable isotopic composition, as well as the average temporal resolution of micromilled subsamples for isotopic analysis varies substantially along and/or within the growth intervals of the sample (Table 2.5 and Fig. 2.6). Overall, the isotopic values in stalagmite MF3 vary between -13.41 ‰ to -6.96 ‰ VPDB for $\delta^{18}\text{O}_{\text{corr}}$ and from - 6.77 to 7.68 ‰ VPDB for $\delta^{13}\text{C}$. For

comparison, in recent deposited calcite (Alpeel Cave, Alpstein Mts.) -7.6 ‰ VPDB for $\delta^{18}\text{O}$ and -0.4‰ VPDB for $\delta^{13}\text{C}$ were measured (dashed lines in Fig. 2.6).

GI	Age interval	Temp. resolution	$\delta^{13}\text{C}$ (‰VPDB)			$\delta^{18}\text{O}_{\text{corr}}$ (‰VPDB)

Table 2.5. Temporal resolution of samples and overview of stable isotopic composition during each growth interval in MF3.

Figure 2.6. $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ time series for MF3. Green bars indicate growth intervals in the sample.

Warm (interglacial/interstadial) conditions will be reflected in positive $\delta^{18}\text{O}$ and cold (glacial/stadial) phases in negative $\delta^{18}\text{O}$, consistent with the relationship between isotopic composition of precipitation and temperature in temperate continental settings (McDermott 2004; Lachniet et al., 2009; Spötl and Mangini, 2007). At our cave site, the precipitation $\delta^{18}\text{O}$ -temperature relation ($d\delta^{18}\text{O}/dT$) is around $0.7\text{‰}/^{\circ}\text{C}$ (Schürch et al., 2003). Bearing in mind the temperature-dependent fraction of $\delta^{18}\text{O}$ during calcite precipitation ($\sim 0.17\text{‰}/^{\circ}\text{C}$; Tremaine et al., 2011), a positive temperature shift of 1°C will translate roughly into a 0.53‰ change in the $\delta^{18}\text{O}$ of MF3. Having these values as a guideline, the $d\delta^{18}\text{O}/dT$ relationship can be used to support the presence of a glacier above our cave during MIS 6. $\delta^{18}\text{O}_{\text{corr}}$ values from GI_{II} and GI_{III} , lower by 4.5‰ compared to modern $\delta^{18}\text{O}$ values, could therefore translate into changes of up to 8°C in the mean (seasonal) temperature at the cave surface. Present-day mean annual temperature above Schafloch Cave is 2.6°C , and warm season temperature (April-September) is 5.8°C . Although a drop of 8°C in temperature is a first-order temperature approximation, under these conditions most probably permafrost formation will occur, and stop calcite formation in the cave. However, calcite precipitated in Schafloch Cave, strongly supports the presence of a warm-based glacier body above our cave at least during the GI_{II} and GI_{III} .

Although not a direct temperature proxy, $\delta^{13}\text{C}$ values of speleothem calcite are primarily influenced by the type of vegetation and microbial processes in the soil zone. An increase in soil biogenic productivity (plant root respiration and microbial activity in the soil) will result in low $\delta^{13}\text{C}$ values. Dry and cold climatic conditions will have the opposite effect, and may be biased to a more bedrock and atmospheric CO_2 influence (McDermott, 2004; Spötl et al., 2005; Rudzka et al., 2011). In an alpine region, reduced soil thickness and nearly vegetation free conditions above the caves can be expected. This low, or even negligible, input of soil-derived organic carbon into the drip water, combined with increased kinetically controlled fractionation (degassing) could induce $\delta^{13}\text{C}$ as heavy as $+6\text{‰}$ VPDB (Spötl et al., 2004). An overview of the $\delta^{13}\text{C}$ values recorded over the individual growth intervals in MF3 is presented in Table 2.5.

Mean $\delta^{13}\text{C}$ values range from 6.5‰ (GI_{II}) to -5.2‰ (GI_{IV}), and indicate significant environmental changes above the cave during the individual GI periods. In the $\delta^{13}\text{C}$ composition of MF3, two major differences are observed between the calcite precipitated under warm-climate conditions and presumably subglacial conditions: the first show mean $\delta^{13}\text{C}$ values lighter than $+4\text{‰}$ VPDB, while the latter group show mean $\delta^{13}\text{C}$ values heavier than $+4\text{‰}$ VPDB. Positive $\delta^{13}\text{C}$ values are attributed to alpine vegetation and soil developing in the area as a direct result of favorable climate-induced conditions. High $\delta^{13}\text{C}$ are attributed to the lack of soil-derived C input into the subsurface (vegetation and soil free conditions), and locally, kinetically induced fractionation plays a significant role (as discussed in sub-chapter 4.2.1).

Based on the measured $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values in MF3, and considering similar isotopic patterns described by Spötl et al. (2007) in speleothems from the high altitude Spannagel Cave (2200-2500 m a.s.l., Zillertal Alps, Austria), we identified the following climatic and environmental scenarios for the individual growth intervals:

- GI_{I} , GI_{VI} , and GI_{VII} show high $\delta^{18}\text{O}_{\text{corr}}$ (average ranging from -8.96 to -8.61‰) and low $\delta^{13}\text{C}$ (average ranging from -5.20 to 1.9‰), suggesting warm interglacial climate, with soil and alpine vegetation developing above the cave.
- GI_{IV} , GI_{V} , and GI_{VIII} show relatively high $\delta^{18}\text{O}_{\text{corr}}$ (average ranging from -10.5 to -9.45‰) and high $\delta^{13}\text{C}$ (average ranging from 3.16 to 4.51‰), and exhibit the lowest correlation coefficient ($r^2=0.01$), suggesting cool interglacial or interstadial climate, most probably without soil cover above the cave.

- GI_{II} and GI_{III} show low $\delta^{18}O_{corr}$ (average ranging from -11.89 to -12.43 ‰) and high $\delta^{13}C$ (average ranging from 4.57 to 6.53 ‰) and exhibit a highest correlation coefficient ($r^2=0.64$), characteristic of a cold stadial climate, a glacier above the cave and limited water availability.

One of the questions is if $\delta^{18}O$ represents a mean annual temperature proxy or is biased towards one of the seasons. For the interglacial and deglaciation intervals, we speculate a mixing between precipitation originating from both seasons. Using present day conditions as a reference, snow cover persists until late spring and its melting will feed the aquifer together with the warm season precipitation and snow meltwater (which will be enriched in $\delta^{18}O$ due to evaporation and sublimation). When the aquifer was fed by a glacier body (glacial and/or interstadial intervals), melting (if any) occurred during the warm season. The isotopic composition of the meltwater feeding the aquifer could depend on the i) degree of water mixing that originated from different parts of the glacier, ii) turnover time of the ice (could be several thousand years, Spötl et al., 2008), iii) dominant season of snowfall and glacier accumulation over different time intervals and iv) changes in the moisture source and moisture path. For the present study time of interest, we are not able to address these issues. Nevertheless, although it is more difficult to interpret these $\delta^{18}O$ depleted values in terms of absolute temperatures, a clear first-order structure of the isotopic profile gives valuable indications on the temperature evolution at the surface at a centennial time-scale, as well as the contribution of glacier or precipitation water into the karst aquifer (Fig. 2.6).

2.4.3. ORGANIC MATTER AND TRACE ELEMENTS CONCENTRATION

2.4.3.1. ORGANIC MATTER CONCENTRATION

At a time of ice-free conditions above Schafloch cave, climate-controlled changes in soil type, vegetation and biological activity can be traced by changes in the organic matter (OM) in stalagmites (Baker et al., 1996; Baker and Genty, 1999; Perrette et al., 2005; Blyth et al., 2008 and references therein; Linge et al., 2009). From the overlying soils, organic matter is transported as colloids (Fairchild and Treble 2009) by percolating meteoric water from which the speleothems are precipitated. It is located between crystals or within small pores in the crystal structure (Ramseyer et al. 1997) and can be observed as photoluminescence when exposed to UV light (Shopov, 2004). The main organic matter molecules present in speleothems are humic and fulvic acids, with the humic acid (originating mostly from soil) displaying a higher intensity of photoluminescence (White, 2004; van Beynen et al., 2001). Over long time intervals, changes in intensity are therefore suggested to represent long term changes in the soil and vegetation (degree of organic matter degradation in the overlying soil), closely related to temperature and water excess (that controls the residence time of organic molecules in the soil (Backer and Genty, 1999). In subglacial waters one will expect the absence of humic substances, likely an outcome of i) low rates of production by microbial communities and ii) rapid flushing during periods of high flow (Foreman et al., 2013).

In the top 8 cm of MF3, changes in the luminescence intensity were observed under UV light. (Fig. 2.7) No absolute measurements of the intensity were performed. We used lower intensities (light color) as an indicator of low organic matter concentration, and high intensities (dark color) for high organic matter concentration (van Beynen et al, 2001). As presented in Fig. 2.7, changes in the organic matter content were observed between and within individual GI in the sample. The highest content of organic matter was observed during GI_{VII} . During GI_{VI} , GI_{IVa} , and GI_{II} the intensity dropped and flat-topped fluorescent laminae are observed. During GI_V , GI_{VIb} and GI_{III} , organic matter is exclusively present

as irregular low-intensity fluorescent bands, and most of the calcite presents no color (white) under UV light.

There is a strong relation between the luminescence intensity and $\delta^{13}\text{C}$, implying that the two records are dominantly forced by closely related processes. We could not find any relation between the luminescence intensity and soil-derived trace elements (e.g. P and Y), due to their strong bimodal source, as discussed later.

Figure 2.7. Thin section of sample MF3, view under microscope and UV light. Arrows indicate location of discontinuity horizons (hiatuses)

2.4.3.2. TRACE ELEMENTS CONCENTRATION

Fairchild et al. (1998) demonstrated that trace element (TE) ratios available in the cave waters correspond to the reaction time between water and bedrocks. Although state-of-the-art laboratory techniques allow us to analyze a large suite of trace elements, processes that govern their incorporation on/within the calcite structure have been studied in detail and reported in literature. In the present study, we used Sr, U, Mg, Ba, P, Si, Fe, Y, and Al considered as reliable proxies for surface environmental changes that occurred above Schafslösch Cave.

To track changes in soil activity and vegetation productivity, we used P concentration. Nevertheless, variations in P could reflect also i) increase in colloidal transport from the soil and low or negligible prior calcite precipitation (PCP) following effective recharge of the aquifer, ii) a response to piston flow effects caused by effective recharge following dry intervals, iii) dissolution features and microbial processes, as a result of long dry phases (Treble et al., 2013; Fairchild et al., 2001; Treble et al. 2003; Borsato et al., 2007). The last ones are shown to have a negligible effect on the overall hydrologically-induced changes in P concentration (Frisia et al., 2013).

To track changes in the karst hydrology, we used the concentration of lithogenic trace elements (e.g. Ba, Mg, Sr, U), known to be dependent on dissolution and mobilization processes (e.g. effective rainfall and residence time in the rock body above the cave, Roberts et al., 1998; McDonald et al., 2004; Zhou et al., 2005; Fairchild and McMillan, 2007; Demarchelier et al., 2006). Treble et al. (2003, 2005) suggest that Sr concentration depends on stalagmite growth rate and soil processes. A high concentration of Ba, Mg, Sr, and U is caused by a longer residence time of water in the aquifer above the cave (Hellstrom et al., 2000; Baldini et al., 2002; McDonald et al., 2004; Johnson et al., 2006). The positive correlation between Sr and Mg can indicate PCP at times of low effective moisture (McDonald et al., 2007; Fairchild and McMillan, 2007).

Several other trace elements such as REE (e.g. Y) and metals (e.g. Ti, Al) are reported to be related with groundwater dynamics. These are common in so-called “impulse laminae” (Richter et al., 2004; Schimpf et al. 2011; Dasgupta, S., 2010; Borsato et al., 2007; Zhou et al., 2008), representing enrichments

in colloid-transported events as a response to high infiltration events, or fracture fed flow. Ti for example is often used as a tracer for detritus, due to its extremely low solubility (Fairchild and Baker, 2012).

The references given above are mostly related to sites where drip water originates from rain and snow melting. As discussed in chapter 4.1, drip water at our site originated not only from these sources, but also from subglacial meltwater. Evolution of landscape (by erosion and weathering), highly influenced by glacial and periglacial processes, will have an influence on the concentration of elements in the (melt) water entering the karst aquifer. During prolonged cold periods, the solifluction (seasonal and diurnal freezing) intensifies and reduces soil thickness and vegetation. In this case, substantial amounts of fine-grained sediment is expected to increase in the waters feeding the karst aquifer (Meyer et al., 2012 and references therein). Ultimately, during the glacier formation the overriding source of trace elements may shift from soils and host rock towards a source which is highly influenced by the mineralogy of fragments derived from glacial abrasion and comminution. Water in the subglacial environment can be a powerful agent of chemical weathering as low temperatures facilitate enhanced solubility of CO₂ in water (Bögli, 1980; Ford and Williams, 2007), and an abundance of freshly ground rock powder provides a constantly renewing source of susceptible minerals. The processes that govern the incorporation of elements in the parent fluid are not extensively addressed in literature, and even fewer examples are given for limestone dominated accumulation areas (Felix and Hallet, 2002.). Nevertheless, several assumptions can be made. Generally, we expect that the meltwater will be rich in a range of solutes (depending on the geological setting) derived from i) precipitation or dry deposition from atmospheric sources, ii) interaction between water and material within the glacier or iii) interaction with soluble materials at the base of the glacier (where most of the solute load is located, Brown and Fuge, 1996). While coarser material can be filtered out in the vadose zone, the elements transported as colloids (e.g. Fe, Si, Al) will reach the stalagmite surface and be incorporated in the calcite structure (Meyer et al., 2012).

An overview of the mean concentration (9 points running average) for each growth interval is presented in Table 2.6. Mg concentration varies from 34 to 4775 mg/kg (min 9 and max 5757 mg/kg). Sr varies from 351 to 968 mg/kg (min 247 and max 1100 mg/kg). U varies from 5 to 12 mg/kg (min 2 and max 26 mg/kg). Ba varies from 16 to 27 mg/kg (min 6 and max 41 mg/kg). P varies from 158 to 527 mg/kg (min 79 and max 974 mg/kg). Y varies from 0.3 to 1.4 mg/kg (min 0.1 and max 7.5 mg/kg). Al varies from 5 to 1771 mg/kg (min 1 and max 4534 mg/kg). Ti varies from 4 to 16 mg/kg (min 2 and max 171 mg/kg). Si varies from 485 to 2893 mg/kg (min 311 and max 18681 mg/kg). Fe varies from 74 to 258 mg/kg (min 29 and max 3248 mg/kg). In the absence of studies regarding modern water chemistry in Schafslösch Cave, we used the values measured during GIVII as reference TE concentrations for an interglacial phase, the geomorphologic architecture and characteristics of karst aquifer above the cave during this time interval are not known. During GIVII barely any strong correlations between the analyzed trace elements are visible (Table 7, GIVII). We observed a positive correlation between Sr and U ($r^2=0.31$) and Sr and Ba ($r^2=0.42$), and K and Si ($r^2=0.67$) as detrital-related elements, although the calcite presents the lowest concentration of detrital and soil related trace elements, as well as in lithogenic ones (Table 2.7).

Concentrations of Sr, U, Mg, Ba, P, Si, Fe, Y, and Al are reported in Fig. 2.8 against a time scale based on linear interpolation between reference age analogues with the stable isotopes profile. Overall, we lack coherence between the MF3 trace element record (see Table 2.7 and Fig 2.8), suggesting very different processes and sources influencing TE concentration. Nevertheless, along individual GI there is an amount of structure, if one considers for example the co-variance among detrital-related (Si, K, Ti, Al) and alkaline-earth elements (U, Sr, Ba).

Several general observations were made based on the trace elements data:

- Sr, Ba and U have closely related signals ($r^2 = 0.42$ to 0.75 , see Table 2.7 and Fig 2.8), implying similar processes influence their concentration change overall. There is no reason to doubt that their concentration in the sample originates mainly from dissolution processes that took place in the host rock. A small detrital (or similar source) contribution during GI_{III} and GI_{IVa} was observed based on positive correlations with Si, Al, Fe and P (r^2 from 0.33 to 0.72). It is likely that the last one took place when more host rock erosion occurred.
- Except the GI_{IVa} and GI_{IVb} , a negative correlation between Sr and P is observed (r^2 from -0.27 to -0.58). P is known to be a strong inhibitor of growth rate, and can change precipitation rate significantly (Meyer, 1984), inducing changes in the partition coefficients of other growth rate dependent elements (e.g. Sr, Tesoriero and Pankow, 1996).
- The Mg profile has a rather complex pattern, displaying no consistent positive or negative correlation throughout the overall dataset with any of the other lithogenic elements or detrital-related elements.
- Highest correlation between detrital trace elements (Fe, Ti, Al, K, Si) is observed during G_I (r^2 from 0.38 to 0.98), G_{III} (r^2 from 0.68 to 0.85) and GI_{IVa} (r^2 from 0.72 to 0.97), and GI_{IVb} (r^2 from 0.32 to 0.77). Considering their absolute concentrations, most host rock erosion is indicated during G_I , the second half of G_{III} and G_{IV} (no data are available for G_V and G_{VI}).
- The path and/or the origin of the percolating water changed during the second half of GI_{III} and GI_{IV} (we have no trace element data for GI_V) to a source area with higher contact to K, Fe and P rich mineral deposits. This is not peculiar, as phosphate minerals of the apatite group and glauconite (iron potassium phyllosilicate) are widely present in the rocks surrounding our cave site (Geologischer Atlas der Schweiz, 1982)

Table 2.7. Trace elements correlation matrix for the growth intervals listed in Table 2.6. In light blue (red) positive (negative) correlation $r^2 < 0.5$ and dark blue (red) positive (negative) correlation $r^2 > 0.5$.

During interglacial conditions (e.g. GI_{VI} and GI_{VII}) high organic matter concentrations were observed and overall the smallest detrital contamination of the sample. P between 110 and 239 mg/kg (9 points r.a) characterize conditions of soil and vegetation presence above our cave. This is in agreement with indications of favorable temperatures (based on $\delta^{18}\text{O}$ values, Table 2.5) and low water retention in the bedrock (based on low Sr, Ba and U concentrations, Table 2.6). By contrast, high variability in organic matter content and trace element concentration is observed during G_{II} to GI_V, reflecting a dynamic glacial and periglacial environment above the cave. Repeated changes of the glacier state from cold to warm-based (experienced as a result of “warm spells” at our cave site) are reflected in sporadic episodes of calcite regrowth. These episodes of calcite ceasing and regrowth during are indicated by a highly irregular development of fluorescent laminae (e.g. GI_{IVb}, GI_V) and a higher concentration of trace elements as K, P, Al after long intervals of accumulation in the bedrock as a result of limited (if any) water availability (high U, Ba, Sr concentration).

Contrary to GI_{IVb} and GI_V, during G_{III} a continuous meltdown process is indicated by flat topped and homogeneous developed fluorescent laminae. With general conditions of atmospheric cooling, high glacial erosion at the surface of the cave (glacier advance) and low water availability in the epikarst are suggested in the older half of G_{III} (high P, Y, Sr, U concentration). Changes towards less erosion and dissolution processes occur in the youngest part of this interval (lower P, Y concentration). These conditions persisted during G_{II}, although more limited water availability in the aquifer is suggested.

Phases of fast meltdown of the glacier body, as a direct result of strong positive changes in temperature during GI_{IVa} and GI_I are clearly indicated by the drops in the concentration of U and Sr, along with an increase in metal concentration (Fe, Al) and organic matter composition (Table 2.6 and Fig. 2.8).

Figure 2.8. Age model of trace element concentrations in MF3 together with stable isotopic composition of calcite, and environmental reconstruction above Schafsfloch Cave

2.5. DISCUSSION

2.5.1. LOCAL PALEO-HYDROLOGICAL AND ENVIRONMENTAL RECONSTRUCTION

Although highly discontinuous, our record allows the construction of a detailed chronology of climatic conditions in the Alpine region. Based on independent proxies and a precise chronological framework, the Schafslösch Cave record provides important clues regarding processes about the cave (e.g soil evolution, erosion history, favorable conditions of glaciers advance and retreat) of local and regional importance.

We stress that the timing of hiatuses in our sample can be related to either one of the following causes: i) specific site conditions above the cave and in the epikarst (high drip rate, drip water outside equilibrium, blockage of drip water pathways or lateral drift of the drip point), and ii) climate-induced changes in water availability (permafrost conditions or cold based glacier above the cave) and isotopic composition of local precipitation. As local site conditions can bias the growth of a single speleothem and mislead the interpretation of the proxies, caution is required when integrating records from multiple sites to distinguish regional climatic signatures from local variations. No coeval sample is available from surrounding area of the Alpstein Mts. Therefore, for a meaningful paleoclimate reconstruction we will refer here to well-documented isotopic records and growth intervals of speleothems from the Austrian Alps (Spannagel Cave; Spötl et al., 2008; Spötl and Mangini, 2010), and lower altitudes caves from Italy (Tan che Urla and Corchia Cave; Regattieri et al., 2014; Drysdale et al., 2009), France (Villars and Clamouse Cave; Planges et al., 2002; Wainer et al., 2011) and Spain (Gitana Cave; Hodge et al., 2008, Fig. 1). The temporal coverage of the MF3 isotopic record falls within the pollen-based sequences of Meikirch 1, 2 and 3 Interglacial (MIS 7), separated by Birchli, Chutzen and Hubel Stadials (Meikirch profile, Swiss lowlands, Preusser et al., 2005). However, based on the author's description, the Swiss record lacks any feasible pollen-based correlation with other European Middle Pleistocene vegetation records. For this reason, for quantitative climate indicators, we will refer to the well-characterized European pollen record of the Iberian Peninsula (Rocheaux et al., 2006), which is in broad agreement with similar records from France (Beaulieu et al., 2001), Italy (Follieri et al., 1988) and Greece (Tzedakis et al., 2004).

2.5.2. MIS 7

As mentioned before, MF3 was displaced from its original growth location and its base could not be analyzed. The oldest measurements in this sample were performed on a 1.3 ka long growth interval, between 225.8 - 224.5 (± 2.3) ka BP. One could attribute the 2 ‰ drop in $\delta^{18}\text{O}$ at around 224.5 ka BP, to the end of MIS 7.5 (7e) warm interval and the transition into MIS 7.4 (7d) cold stadial. This timing is in disagreement with evidence from Spannagel Cave (Austria), that indicate a much earlier onset of stadial conditions in the region already around 240 ± 3 ka BP (Spötl et al., 2008, Fig. 2.9). Furthermore, regional climate was altered as a direct result of falling sea surface temperatures (SST) in the North Atlantic region and increasing global ice volume after an insolation minimum around 230 ka BP (Roucoux et al., 2006). For this reason, it is unlikely that interglacial conditions at Schafslösch Cave prevailed until around 225.8 ka BP. Therefore, we suggest that interstadial conditions in the region occurred between 225.8 - 224.5 (± 2.3) ka BP, well supported by local evidence of (if any) sparse soil above the cave. Evidence of this warm spell are observed in a warm fluctuation recorded in the Iberian pollen profiles (MD47-7-5, Desprat et al., 2006) and SST fluctuations (Martrat et al., 2007).

After a 4.4 ka long hiatus in the sample, calcite started to form after 220.1 ± 1.4 ka BP. This coincides

with the start of high precipitation rates over the Iberian Peninsula between 212-221 ka BP (Desprat et al., 2006). The isotopic profile of MF3 covers the last part of the MIS 7.4 (220.1 to 217.7 ± 1.4 ka BP) and the 800 year-long transition into MIS 7.3 (7c) in high detail. This transition towards the warm interglacial conditions of MIS 7.3 (7c) is marked by a 1.7 ‰ step-like shift in $\delta^{18}\text{O}$, between 216.5 - 217.7 ka BP (midpoint at 216.7 ± 1.4 ka BP), and an 6 ‰ negative shift in $\delta^{13}\text{C}$ due to rapid soil formation and vegetation development above the cave. Warm and wet interglacial conditions seem to prevail until 211.1 ± 1.4 ka BP. Between 211.1-207.5 ± 1.4 ka BP a drop in the growth rate, followed by positive shift of 3 ‰ in $\delta^{13}\text{C}$, mark the deterioration of environmental conditions above the cave. This vegetation decline, similar to the expansion of dry-grassland in the Iberian Peninsula between 208-212 ka BP (Desprat et al., 2006), suggest a water deficit (if not also temperature a drop) at our site, as proven by the slow growth rate of the sample. Between 205.2 - 207.5 ± 1.4 ka BP the growth rate of MF3 rises again, as a result of increased water availability (presence of filled macroscopic pores with microcrystalline calcite which suggest a faster drip rate). The 1‰ gradual negative trend in $\delta^{18}\text{O}$ indicates a temperature decline over this time interval, as soil and vegetation density remains low compared to the first part of MIS 7.3. A well-defined hiatus at 205.5 ± 1.4 ka BP marks the transition into MIS 7.2 (7b) cold stadial, although no significant drop in $\delta^{18}\text{O}$ is observed. Still, the age is again in good agreement with regional evidence. Both the onset and end of MIS 7.3 in MF3 (216.7 ± 1.6 ka BP and 205.5 ± 0.9 ka BP), agrees very well with the SPA record (215.0 ± 3.0 ka to 232.0 ± 3.0 ka BP, Spötl et al., 2008, Fig. 2.9) within errors.

Between 199.7 to 205.2 ka BP the sample growth ceased, influenced by the cold stadial conditions occurring during MIS 7.2 (7b). Calcite deposition restarted during MIS 7.1 (7a). This last warm phase of MIS 7 is represented by two growth intervals in MF3, between 198.5 - 199.7 ± 1.7 ka BP and $185.9 - 189.1 \pm 1.4$ ka BP. The timing of the 0.6 ‰ positive shift in $\delta^{18}\text{O}$, between 198.5 - 199.7 ± 1.7 ka BP, agrees well with the onset of interglacial conditions in the Austrian Alps (SPA 121 record) at 200 ± 3 ka BP. Negative $\delta^{13}\text{C}$ values (-6.7 to -1.2 ‰ VPDB) and high organic matter content in the calcite suggest a well-developed soil and vegetation above the cave during early MIS 7.1. The cessation of calcite growth between 189.1 ± 1.4 and 199.7 ± 1.9 ka BP is most likely related with changes in the local hydrological regime. None of the regional climatic reconstructions (e.g. Spannagel Cave record) suggest a major climatic reorganization at this time.

Between $185.9 - 189.1 \pm 1.4$ ka BP (late MIS 7.1) a 3.1 ‰ negative shift in $\delta^{18}\text{O}$, a gradual 7 ‰ increase in $\delta^{13}\text{C}$ and almost no organic matter content in the calcite, track temperature alteration and environmental changes above the cave, from warm interglacial towards cold glacial conditions (Fig. 2.6 and Fig. 2.7). The organic matter content and $\delta^{13}\text{C}$ values in this part of the sample suggest calcite precipitated in subglacial environment, in agreement with indications of cold and humid climate on the Iberian Peninsula (Desprat et al., 2006), and suggests a glacial advance above Schafloch Cave at around 187.0 ka BP. In the absence of ice above our cave, we would expect a higher concentration of detrital-related particles in the calcite structure (see for example GI_{IVa} , discussed below). An intermittent growth of the sample is suggested by the irregular development of fluorescent laminae (Fig. 2.7), in good agreement with indications of repeated cold - warm fluctuations of relatively large amplitude during the MIS 7 / MIS 6 transition (Roucoux et al., 2006; Martrat et al., 2006).

Calcite growth ceased after 185.9 ± 1.6 ka BP is most probably related to a cold-based shift of the glacier or freezing of the cave. This marks the transition into the penultimate glaciation (MIS 6) at our site, well within age estimates reported from Spannagel Cave (SPA 52, 188.7 ± 2.8 ka BP, Spötl et al., 2008) and (Cla4 188.2 ± 1.5 ka BP, Planges et al., 2002, Fig. 2.9).

Figure 2.9. Comparison between $\delta^{18}\text{O}$ of Schafsloch Cave (our study) and $\delta^{18}\text{O}$ of Spannagel Cave (Spötl et al., 2008), Tanache Urla (Regattieri et al., 2014), Corchia Cave (Drysdale et al., 2009), together with growth intervals (horizontal green rectangles) of samples from Gitana Cave (Hodge et al., 2008), Clamouse Cave (Planges et al., 2002), Villars Cave (Wainer et al., 2011) and Spannagel Cave (Spötl and Mangini, 2010, please note that for a clear comparison only the age of important isotopic shifts, together with their error are presented). Vertical light green boxes represent growth intervals in sample MF3.

2.5.3. MIS 6

2.5.3.1. LOCAL SCALE ENVIRONMENTAL CHANGES

The presence of the glacier is recognized all across MIS 6 interval. Its dynamics (advance, erosion and/or retreat above the cave) is documented as chemical changes in the calcite of MF3 sample. During MIS 6, calcite formed in the cave between 181.1 - 183.3 \pm 1.4 ka BP, 151.9 - 161.2 \pm 1.0 ka BP, 137.4 - 133.0 \pm 0.5 ka BP, and 131.9 - 130.1 \pm 0.4 ka BP (respectively GI₁ to GI_{IVb}). High chronological uncertainty is attributed to the 6 mm highly-corroded calcite attributed in our age model to the interval 180.2 - 181.15 ka BP.

The localized extension of calcite precipitated during 181.15 - 183.3 ka BP suggests extremely limited water availability at a time of cold climate conditions. Repeated changes in the thermal state of the glacier and water availability are indicated (similar with the 185.9 - 189.1 ka BP interval) by irregular fluorescent laminae and short-term high amplitude variation in the concentration of elements like P, Fe, Al and U (Fig. 2.8). During 180.2 - 181.15 ka BP interval conditions change drastically, as positive modifications in the hydrological regime (high water availability suggested by U, Sr, Ba low concentration), temperature (around 1.2 ‰ shift in $\delta^{18}\text{O}$) and a high detrital and organic matter concentration in calcite (Fig. 2.7) suggests the deglaciation of the area within 300 years. Without any indication of soil formation (high $\delta^{13}\text{C}$) and based on the presence of horizontal fluorescent bending in the calcite, we speculate an increased input of fine detrital material into the drip water, with its source in the erratic siliciclastic material overlying the cave after the glacier retreat. Three well-defined corrosion laminae suggest interruption of growth. Responsible processes could include the following: i) a rapid passage of water through the epikarst (allowing little dissolution of bedrock CaCO_3 , drip water may not have reached equilibrium with respect to Ca, Railsback et al., 2013), ii) condensation-corrosion of the calcite during “dry”/“cold” intervals and calcite ceasing (Lauritzen 1995) or iii) flooding of the gallery and water-corrosion of calcite surface (Martin-Garcia et al., 2011).

Conditions at the surface change again between $151.9 - 161.2 \pm 1.0$ ka BP, with low isotopic values ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) and lack of organic matter in calcite indicating a re-advance of the glacier between these two growth intervals. Very slow drip rates and intervals of strong degassing of CO_2 are suggested by the precipitation of calcite under disequilibrium conditions. Less complex layering of the fluorescent layers indicate a constant but slow drip rate and recharge of the aquifer above Schafslösch Cave, and no indication of a long absence of calcite deposition are observed during this time interval. Between 151.9 - 137.4 ka BP the glacier returned to its cold-based state.

Based on isotopic and TE evidences, we suggest a slow melt of the glacier starting with 137.4 ± 1.4 ka BP, followed by a return to cold-based conditions between 133.1 ± 0.7 to 131.9 ± 0.6 ka BP, followed by a rapid melting down of the glacier. Enhanced contribution of snow/rain water as a result of temperature increase is suggested by the abrupt change in $\delta^{18}\text{O}$, and pioneering soil and vegetation development are suggested at 131.7 ka BP. The columnar calcite, in combination with diffuse fluorescent properties of the calcite and absence of fluorescent banding suggest again a slow, but continuous feeding of the aquifer. The very low drip rates in combination with occasional high discharge events prevented seasonal karst water pulses to reach the drip point and rather facilitated mixing of seasonal surface signals (Meyer et al., 2012). Chemical changes in the calcite between 137.4 and 130.1 ka BP, local and regional environmental implications are discussed in detail in Chapter 3.

2.5.3.2. INTEGRATION ON A REGIONAL AND HEMISPHERIC SCALE DURING MIS 6

Indicators of climate amelioration during MIS 6 was already recognized in the region, based on calcite deposition in several European caves in France, England and Slovakia (Plagnes et al., 2002 and citation therein). Speleothem growth is reported in France and England, starting at 177.7 ± 3.0 ka BP in Villars Cave (45°N, Wainer et al., 2011), between 162.3 ± 1.5 and 169.1 ± 1.5 ka BP in Clamouse Cave (43° N, Plagnes et al., 2002), and around 168 ± 3.4 ka BP in Stump Cross caverns (54°N, Baker et al., 1996). On the southern side of the Alps, detailed isotopic records from the Tana Che Urla and Corchia Cave (both 44°N, Regattieri et al., 2014; Drysdale et al., 2009) cover the time interval starting at around 159.1 ± 1.3 ka BP. The only record covering the entire MIS 6 interval is reported from Gitana Cave (37°N, Hodge et al., 2008). Spannagel Cave reports calcite growth between 173.6 ± 1.8 and 176.1 ± 2.4

ka BP (SPA 121, Spötl et al., 2008) and 179.7 ± 1.5 ka BP (top of SPA 146, Spötl and Mangini, 2010, Fig. 2.9).

At a local scale, glacial deposits of the Rhine paleoglacier in the Alpine foreland suggest at least two main glacial advances during MIS 6, separated by an interstadial phase (Graf, 2009; Preusser et al., 2011; Lowick et al., 2015). If one agrees with the robustness of our age model, changes in the thermal state of the glacier overlying Schafsfloch Cave between $180.2 - 183.3 \pm 1.4$ ka BP and $151.9 - 161.2 \pm 1.0$ ka BP brings therefore new insights in the regional climate during this interval.

Firstly, we will discuss the evidence that relates to a regional climatic amelioration between $180.2 - 183.3$ ka BP, and propose an alternative age estimation for the younger calcite precipitated in Schafsfloch Cave during this growth interval (GI_{IV}).

Around 180 ka a brief decrease in $\delta^{13}C$ of 3‰ VPDB marks a pulse to warmer and wetter conditions in southern Spain (Gitana Cave, Hodge et al., 2008). Other archives suggest increased moisture and warmth availability in S-W Europe (MD01-2443, Roucoux et al., 2006; Völker et al., 2011), coeval with a light excursion in planktonic $\delta^{18}O$ (SST warming) and a pause in the positive trend of benthic $\delta^{18}O$ (MD01-2443, Roucoux et al., 2006). These data can be corroborated with evidence of a sea level high stand lasting 5 to 10 ka after the 190 ka BP peak in MIS 7.1. Thompson and Goldstein (2005, 2006) and Henderson et al. (2006) suggest a MIS 6/7 mid-point at 184 ka BP, with a maximum extension of the warm interval to 180 ka BP (Roucoux et al., 2006; Henderson et al., 2006). This period of warmth in S-W Europe is consistent, within error, with the light isotopic excursion in our sample, between $181.15 - 183.3 \pm 1.4$ ka BP (GI_{IVb}).

Around $180.22 - 181.15 \pm 1.4$ ka BP (GI_{IVa}), evidence of strong local changes in temperature (and retreat of a glacier body) are difficult to reconcile with a decreasing trend in SST and land temperature as suggested by the archives listed above. Taking this into consideration, and emphasizing the lack of a direct ^{230}Th age control, we propose an alternative age for the 6 cm highly-corrosive and organic matter-rich calcite, around 175 ka BP. Precipitation of calcite in Schafsfloch Cave is coeval with calcite precipitation in both low- and high- altitudes of western and Central Europe (Spannagel, Villars and Clamouse Cave; Plagnes et al., 2002; Spötl et al., 2008; Wainer et al., 2011, Fig. 2.9)

Calcite forming in Schafsfloch Cave between $151.9 - 161.2$ ka BP is in excellent agreement with evidence of climate amelioration and enhanced precipitation south of the Alps (Tana che Urla Cave, Regattieri et al., 2014) between 159.1 ± 1.3 ka BP and 152.1 ± 1.9 ka BP. This 9 ka long interval of glacier reorganization above our cave is in line with a significant retreat of the southern margin of Scandinavian ice sheet, and a large scale-scale melt-water event was recorded in deep-sediments from Bay of Biscay (NE Atlantic, Toucanne et al., 2009) between 150-160 ka BP. Alpine glacier meltwater input in the Pô River at around 150 ka was reported by Piva et al., 2008. Pollen evidence suggest interstadial conditions between 151-157 ka in Spain (Roucoux et al., 2006), and a short-lived increase in arboreal pollen in N Greece occurred around 150 ka (Tzedakis et al, 2003, SPACMAP tuned chronology).

Finally, one might assume that this interval ($151.9 - 161.2$ ka BP) of network break-down in the Alpstein glacier is coeval with a retreat of the main glaciers advancing towards the low-land regions north of the Alps, as suggested by previous studies. This retreat can also be related to precessional forcing which increased both summer insolation and seasonality (related to severe winters and warmer summers).

2.5.4. INTERNAL AND EXTERNAL FORCING ON ALPINE CLIMATE OVER MIS 6 AND MIS 7

We have shown that growth intervals in our sample are related to positive temperature changes in the Alpstein Mts. that induced either changes in the isotopic composition of the snow/rain during interglacial interval MIS 7 or changes in the thermal state of the glacier above Schafsloch Cave during glacial interval MIS 6. By using the temporal reconstructions of glacier dynamics and isotopic changes in the sample, we can evaluate the contribution of individual climate forcing (orbital and feedback of internal sea-ice-atmosphere system) over millennial-scale climate cycles.

Northern Alpine glaciers are sensitive to changes in warm season temperatures, which control the position of the equilibrium line and determine if the glacier has a positive or negative mass balance (Huss et al., 2008). Apart from the radiation budget received during the warm season (a function of precessional and obliquity cycles), the local climate is also influenced by changes occurring in the North Atlantic region and its atmosphere-ocean system, whereas climate variables in the North Atlantic region, such as the position of polar front, sea ice and formation of deep water (NADW) are influenced by the northern hemisphere ice sheet extent (Hodell et. al, 2013).

We compared our data with both variations in orbital parameters (Berger and Loutre, 1991) and reported evidence of oscillations in sea level (relative sea level, Rohling et al., 2009), formation of NADW (Völker et al., 2011), sea surface temperature (SST, Martrat et al., 2009) and atmospheric changes in greenhouse gas concentration (Loulerge et al., 2008).

The northern alpine climate during MIS 6 to MIS 7.3 appears to respond to both a rise in summer insolation and oceanic reorganization (Fig. 2.10). For the radiative budget, following the approach of Carlson and Winsor (2012), we have used mean boreal summer insolation from May to July (Fig. 2.10, red line, Berger and Loutre, 1991). The timing of these changes precedes changes in July insolation at 65°N (Fig 2.10, orange line, Berger and Loutre, 1991) by 2-3 ka. Overall, the MF3 $\delta^{18}\text{O}$ record does not display a consistent pattern with the variations in summer insolation, as observed for example in well-documented records from Asia or North America (Lachniet et al., 2014; Cheng et al., 2012 and references therein). During MIS 6 and T-II changes in the thermal state of the glacier follow positive changes in summer insolation shortly after minima in insolation (at 138 ka, 163 ka and 187 ka BP). Warming in the region follows the rising limb of insolation, with relatively weak precessional forcing strengthened by strong obliquity values (high seasonality).

During MIS 7 this relationship partly breaks down. Although low insolation around the minimum at 208 ka BP lead to a drop in calcite growth rate (and a possible hiatus occurs), during MIS 7.4 and 7.2 the region experiences cold stadial conditions at times of high summer insolation (500-520 W/m²) and high obliquity. This suggests that other climatic mechanisms and interconnections should be considered.

If comparing the isotopic profile and growth intervals of MF3 sample with hemispheric evidence of internal forcing, our record confirms the relationship between processes over the North Atlantic Ocean (SST, state of NADW, meltdown contribution of ice caps) and alpine climate during 130 to 230 ka BP (Fig. 2.10). Hiatuses in our sample appear to correspond with intervals of slow NADW formation (see positive $\delta^{13}\text{C}$ in core MD01-2334, Völker et al., 2011), low North Atlantic SST (ODP 977a, Martrat et al., 2007) and a low relative sea level (Rohling et al., 2009; Grant et al., 2012). Calcite formation in the Schafsloch Cave occurs at times of change in greenhouse gas atmospheric concentration during MIS 7 and T-II (CH_4 , Loulerge et al., 2008), as amplifier for warming.

For the MIS 6 interval, our data support the findings of Margari et al. (2010) who state that weak forcing (low insolation, obliquity, and green gasses concentration) could trigger major

Figure 2.10. Comparison between $\delta^{18}\text{O}$ of Schafsfloch Cave (our study) and orbital parameters at 50°N and 65°N (Berger and Loutre, 1991), alkenone-based sea-surface temperatures from western Mediterranean core ODP-977A (Martat et al., 2007), formation of NADW (Völker et al., 2011), oscillations in ice cap volume (relative sea level changes, Rohling et al., 2009), and atmospheric changes of the greenhouse gas concentrations (Loulergue et al., 2008)

climate reorganization as a result of very low disruption thresholds in the NADW formation.

A slow resumption of NADW formation and changes in SST will favor increased air temperatures, evaporation and moisture advection across the Mediterranean region (Sanchez-Goni et al., 2012). Advection of warmer air masses (with a significant portion sourced from NAO) towards the north side of the Alps would have been possible via an enhanced southerly circulation (Florineth and Schlüchter, 2000) and/or at times of North Atlantic air masses penetrating towards the east Mediterranean regions (e.g., Plagnes et al., 2002). New records are required from both sides of the Alps in order to better understand these mechanisms. During MIS 6.4 and T-II, enhanced precipitation south of the Alps (Regattieri et al., 2013) match periods of positive temperature changes in the north of the Alps (our study, Fig. 2.9). This relationship breaks down, for example, between $162.3 - 169.1 \pm 1.5$ ka BP, when climatic amelioration is reported from Clamouse Cave data (Planges et al., 2002). Similarly, the beginning of the $\delta^{18}\text{O}$ plateau of MIS 7.3 in the isotopic profiles from Corchia Cave (Couchoud et al., 2011, around 224 ka BP) appears to lead by ca. 7 ka, the one recorded in northern alpine samples (Spötl et al., 2008 and this study). This could also suggest changes in the climate mechanisms influencing both sides of the Alps over glacial-interglacial cycles.

Moving from inter-regional to inter-hemispheric teleconnections, our data seem to agree with a southward displacement of the Intertropical Convergence Zone between 136.7 ± 1.2 ka to 134.5 ± 1.1 ka BP, 177.6 ± 1.7 ka to 182.2 ± 1.6 ka BP, around 205.8 ± 1.9 ka BP, and 207.0 ± 1.6 ka to 209.3 ± 1.8 ka BP (Wang et al., 2004). These intervals are suggested to be synchronous with cold periods in Greenland and Heinrich events in the North Atlantic, and correspond with slow growth intervals and hiatuses in our sample when regional climate experienced cold and glacial conditions.

2.6. CONCLUSIONS

The MF3 stalagmite provides a unique opportunity to investigate a regional expression of millennial-scale climate variability in Central Europe during MIS 6 and Late MIS 7. Based on our results, cave air temperatures above 0°C allowed the (slow) precipitation of calcite in the cave during eight individual growth phases coinciding with warm phases of MIS 7, interstadial conditions of MIS 6, and the transition into MIS 5 (penultimate deglaciation, T-II). Intervals of growth during MIS 6 and depleted oxygen values suggest the cave was thermally protected by a local mountain glacier body during this glacial stage. As no other evidence of its presence is preserved in the environmental archives at the surface, isotopic and trace elements evidence in this speleothem were used to document its dynamics above Schafsfloch Cave. We suggest the Alpstein valley was ice-free during MIS 7 and in the second part of the penultimate deglaciation.

Taken together, growth intervals in MF3 provide a robust record of temperature-induced environmental changes in high alpine sites. The growth rate in the sample slows dramatically (or comes to a halt) at times of relatively large ice-sheet volume and low boreal summer insolation. At times when a glacier body covered the cave, small changes in summer insolation sustained by increased seasonality (high obliquity) triggered changes in the ice body. Nevertheless, the direct relationship between alpine temperature change and insolation values break down partially during MIS 7, suggesting additional triggers and/or mechanisms that should be considered. Generally, similar to present day conditions, we observed a strong influence of sea surface temperature and moisture advection over the continent, at times of enhanced NADW formation. Furthermore, we suggest coupling of climate at the north and south sides of the Alps during late MIS 6 and T-II (Drysdale et al., 2009; Häuselmann et al., in review), which was broke for example during MIS 7 (Couchoud et al., 2011).

3.1. INTRODUCTION

Knowledge about the timing and nature of glacial/interglacial transitions (termed “Terminations”; T hereinafter) is crucial for a better understanding of the complex relationship between external (e.g., insolation) and internal (e.g., ice sheets, greenhouse gases, ocean circulation) climate forcing mechanisms (e.g., Tzedakis et al., 2009; Waelbroeck et al., 2008; Cheng et al., 2009; Drysdale et al., 2009). Dating of terminations prior to the last deglaciation (Termination I), however, remains challenging due to the lack of precise and absolute dating techniques for marine and terrestrial sediment sequences and ice cores covering. As a result, chronologies of almost all palaeoclimate records are based on orbital-tuning, which makes it difficult to reveal the leads and lags between insolation and climatic changes during deglaciations. Independently derived absolute and precise chronologies covering terminations are thus in high demand.

Well-constrained ages for the timing of terminations can be obtained by Uranium-series dated (^{230}Th hereinafter) speleothems and corals. The latter, however, are more prone to diagenetic alteration and remobilization of Uranium (‘open system conditions’) (e.g., Thompson and Goldstein, 2005), and both effects can lead to inaccurate ages. Among all palaeoclimate archives, speleothems have currently the highest potential to deliver absolute and accurate age estimates for the timing of terminations, including the intensively studied T-II at around 130 ka BP. This glacial/interglacial transition is currently covered either in full or in part by several ^{230}Th -dated speleothem records from caves located in different climatic zones. However, the dating accuracy of most of these records is rarely below ± 1.5 ka (2σ -errors) and ^{230}Th -ages are not always in stratigraphic order, making it still challenging to provide precise estimates of leads and lags between these records.

To date, the most precisely-dated record covering T-II is the Sanbao Cave $\delta^{18}\text{O}$ record from China (Cheng et al., 2009), which suggests an age of 129.0 ± 0.1 ka BP for the midpoint of T-II in the Asian monsoon domain. This age estimate is in good agreement with less-precisely-dated stalagmites from Dongge Cave, China, (Kelly et al., 2006), and appears to be broadly consistent with speleothem records from Soreq Cave (Israel) and Sofular Cave (Turkey) (Badertscher et al., 2011; Grant et al., 2012). However, speleothem records from Corchia and TUC Caves (Italy), Nevada Caves (N. America), suggest significantly older ages of 132.6 ± 1.8 and 132.0 ± 0.6 ka BP for the midpoint of T-II (Drysdale et al., 2009; Shakun et al., 2011; Regatieri et al., 2014; Lachniet et al., 2014). Additional speleothem records covering T-II were obtained from Hoti Cave (Oman; Fleitmann et al. 2003), Mukallah Cave (Yemen; Fleitmann et al., 2011), Spannagel Cave (Austria; Holzkämper et al., 2005), Oregon Caves National Monument (USA; Esrek et al. 2009), several caves in the Negev (Israel; Vaks et al. 2010) and Villars Cave (France; Wainer et al., 2011), but their chronologies suffer from considerable age uncertainties and/or reversals, and are thus not well-suited to shed further light on the timing of T-II. Nevertheless, they provide valuable information on the magnitude and nature of regional climatic changes during the penultimate deglaciation.

Additional well-dated speleothem records are therefore needed to reduce the current uncertainties surrounding the timing of T-II and to account for possible site-specific response times of local and regional climate during the penultimate deglaciation. To add further evidence regarding the nature of T-II in central Europe, we present a precisely dated high alpine speleothem $\delta^{18}\text{O}$ record from Schafslösch Cave in Switzerland. High Uranium concentrations of several mg/kg and negligible detrital contamination permit the determination of very precise ^{230}Th -ages with age uncertainties of generally less than ± 0.6

ka. In addition, highly-resolved stable isotope and trace element profiles provide detailed information on changes in temperature, precipitation and ecosystem across T-II at this high alpine cave site. The stalagmite MF3 record covers much of T II in an area that is very sensitive to changes in North Atlantic climate, allowing us to refine our knowledge of the nature of T II in central Europe and the North Atlantic realm.

3.2. SITE AND SAMPLE DESCRIPTION

Stalagmite MF3 was collected from Schafsfloch Cave located in the Appenzell Alps (47°14'N, 9°23'E, 1890 m above sea level (a.s.l.; Fig. 3.1). Climate in this area is strongly influenced by the North Atlantic region, which is the main source of moisture (Sodemann and Zubler, 2010; Wanner et al., 1997). Lapse-rate corrected (0.54°C/100 m) mean annual air temperature (MAAT) at Schafsfloch Cave derived from meteorological station data (1961-2010) from the Säntis (47°24'N, 9°34'E, 2500 m a.s.l.; Fig. 3.1) are around 2.6°C, with winter and summer temperatures averaging -2.5°C and 8.5°C respectively. Precipitation at the cave site is around 2200 mm yr⁻¹. Soil depth above Schafsfloch Cave ranges between a few centimeters to decimeters, whereas vegetation is sparse.

Schafsfloch Cave is situated in the pure planktonic limestone of Seewerkalk Formation, and is covered by ~20 m thick epikarst (bedrock above the cave). Today, only the first 25 m of the cave are accessible, as the inner part is blocked by sediments in which the 215 mm long stalagmite MF3 (Fig. 3.2A) was found. Its original position within the cave is therefore unknown. Stalagmite MF3 is composed by dense and translucent columnar-fibrous calcite. For this study, only the uppermost 33.75 mm of the sample were studied in detail.

Fig. 3.1. Location maps of Schafsfloch and Alpeel Caves (view: Google Earth Maps)

3.3. METHODS

Petrographic observations were carried out using an optical transmission microscope at the Institute of Geological Sciences, Bern, Switzerland.

²³⁰Th-ages were determined on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS, Thermo-Finnigan Neptune) at the Department of Geology and Geophysics, University of Minnesota. Details of the methods, including standards used for mass fractionation and yield correction can be found in Cheng et al. (2013). For analysis, between 70 and 100 mg of powder was drilled along discrete growth horizons (Fig. 3.2B).

For stable carbon and oxygen isotope analysis, a total of 321 samples were micromilled continuously

at 0.1 mm and 0.25 mm increments from 0 to 31 mm and 31 to 34.5 mm, respectively. Powdered samples were measured using a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. Results are reported relative to the international Vienna Pee Dee Belemnite (VPDB) standard. Analytical errors for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ are 0.07 and 0.06 ‰ VPDB (1 σ), respectively (Fleitmann et al., 2009).

Fig. 3.2. *A* Macroscopic view of stalagmite MF3, white lines denote the isotopic (solid line) and trace element (dashed lines) tracks. *B* Macroscopic view of the upper 40 mm of MF3. White dots denote ^{230}Th sampling locations. Discontinuities in the sample are indicated by dashed lines and arrows. *C* Optical microscope image (cross-polarized light) of the top of MF3. Typical calcite fabric in the sample: closed columnar fabric under the discontinuity layer (Hiatus 1, indicated by the white arrow in both images) and opened columnar fabric above it. *D* Optical microscope image under UV light. Fluorescent laminae are observed in the entire section. Above hiatus 1 (H1), at the growth interference of crystals irregular organic matter enriched zones are present. Growth direction of the sample is indicated by the black arrow.

Trace element analyses were carried out using a 193 nm ArF excimer laser (GeoLas Pro, Lambda Physik) coupled to a quadrupole ICP-MS (ELAN 6100 DRC+, Perkin Elmer). Operating conditions are listed in Chapter 2, Table 2.2. A detailed description of the experimental setup has already been given in Kovacs et al. (2010) and was subsequently further optimized as described in Tabersky et al. (2013). In brief, laser ablation was performed in atmospheric ambient air without further sample size reduction. The laser-generated aerosol was pumped into a gas exchange device (J-Science, Japan) by a membrane pump (DSA-2-12BL, Denso Sangyo, Japan) via an in-house built plume entrainment device at a suction flow of 0.8 L/min and afterwards transported into the ICP-MS in an Argon atmosphere. Element concentrations were measured using line scans parallel to the growth axis and isotope sampling tracks. Two cleaning line scans were applied to remove potential contaminations on the sample surface and only the third was used for quantification, which was carried out by non-matrix-matched calibration using NIST SRM 610 as external standard. Additionally, $^{42}\text{Ca}^+$ was used for internal standardization, using the stoichiometry of Ca in carbonates (400 000 mg/kg pure calcite) and values were normalized to 100% sum of oxides, whereas the calcium concentration was normalized to CaCO_3 . Data evaluation was carried out in STALQUANT, an in-house Python-based software program to reduce large amounts of point-by-point quantification data (Fricker, 2012).

Wavelength	193 nm
Crater size	60 μm (aquisition); 120 μm (cleaning)
Scan speed	20 $\mu\text{m/s}$

U decay constants: $\lambda_{238} = 1.55125 \times 10^{-10}$ (Jaffey et al., 1971) and $\lambda_{234} = 2.82206 \times 10^{-6}$ (Cheng et al., 2013). Th decay constant: $\lambda_{230} = 9.1705 \times 10^{-6}$ (Cheng et al., 2013).

* $\delta^{234}\text{U} = ([^{234}\text{U}/^{238}\text{U}]_{\text{activity}} - 1) \times 1000$. ** $\delta^{234}\text{U}_{\text{initial}}$ was calculated based on ^{230}Th age (T), i.e., $\delta^{234}\text{U}_{\text{initial}} = \delta^{234}\text{U}_{\text{measured}} \times e^{1234 \times T}$.

Corrected ^{230}Th ages assume the initial $^{230}\text{Th}/^{232}\text{Th}$ atomic ratio of $4.4 \pm 2.2 \times 10^{-6}$. Those are the values for a material at secular equilibrium, with the bulk earth $^{232}\text{Th}/^{238}\text{U}$ value of 3.8. The errors are arbitrarily assumed to be 50%.

***B.P. stands for “Before Present” where the “Present” is defined as the year 1950 A.D.

3.4. RESULTS

3.4.1. CHRONOLOGY OF STALAGMITE MF3

The age model for the uppermost 33.75 mm of stalagmite MF3 is constrained by thirteen ^{230}Th -dates, all of them are in stratigraphic order within their 2σ dating uncertainties, and based on the StalAge algorithm (Scholz and Hoffmann, 2011; Fig. 3.3). High U content (1.7 to 7.5 mg/kg) and negligible detrital contamination result in very precise ages with age uncertainties of between 0.4 and 0.6 ka (Table 1). Stalagmite MF3 growth started at 137.4 ± 1.4 ka BP (growth phase II), ceased (hiatus H1; for further details see discussion below) between 133.1 ± 0.7 and 131.9 ± 0.6 ka BP, and then continued until 130.1 ± 0.5 ka BP (growth phase I). As expected for a stalagmite from a high alpine region with low mean annual air temperatures, growth rates vary between 0.003 and 0.1 mm yr^{-1} during growth phases II and I respectively.

Fig. 3.3. Age-depth plot for stalagmite MF3. The blue shaded area shows the 95% confidence intervals of the MF3 age model as determined with STALAGE (Scholz and Hoffmann, 2011). Grey vertical bars denote discontinuities, labelled H1 and H2. Roman numerals denote growth phases of stalagmite MF3.

Stalagmite MF3 is composed by columnar calcite. The hiatus at 20.6 mm is characterized by sudden changes in calcite fabric, abundance of fluid inclusions and content of organic matter (Fig. 3.2A). Under UV light this discontinuity is marked by a thin layer of calcite enriched in detrital material and also by a change from a compact columnar (growth phase II) to an inclusion-rich columnar calcite fabric (growth phase I). The top layer of stalagmite MF3 shows no signs of corrosion as the crystal terminations have a regular shape.

Towards the top of the sample, the fabric changes from microcrystalline subtype of columnar fabric to an open columnar inclusion-rich calcite. Under UV light banding is observed in both fabrics, but the content of organic matter (lighter color in Fig 3.2) is considerably higher above hiatus H1. The dense close columnar fabric in growth phase II precipitated at low supersaturation conditions, regular flow and negligible presence of impurities (Frisia et al., 2000). These conditions changed with the beginning of growth phase I, directly related with changes in the growth rates, high supersaturation conditions, presence of impurities and higher drip rate (Frisia and Borsato, 2010, Boch et al., 2011). Fluorescent laminae are observed in both growth phases, they are flat-topped (on less developed crystal terminations) during growth phase II, and enriched fluorescent bands can be observed at the surface of more irregular crystals terminations in growth phase I. This may be the result of a thick film of water on the surface of the growing stalagmite, together with a higher input of organic matter and detrital material in the sample.

3.4.2. STABLE ISOTOPES

The temporal resolution of the oxygen and carbon isotope profiles varies between 6 and 40 years (Fig. 3.4). Both isotope profiles show distinct trends, with $\delta^{18}\text{O}$ values increasing by 3.2 ‰ and $\delta^{13}\text{C}$ values decreasing by 9.3‰ across the penultimate deglaciation. Isotope values for growth phase II vary between -11.9 to -10.8 ‰ for $\delta^{18}\text{O}$ and +6.1 and +7.5 ‰ for $\delta^{13}\text{C}$. In contrast, growth phase I is characterized by a steep rise in $\delta^{18}\text{O}$ from -10.3 to -8.2 ‰, whereas $\delta^{13}\text{C}$ values show an opposite shift, from +6.9 to -1.5‰ VPDB. Second order variations of around 0.5‰ are apparent in both isotope profiles.

3.4.3. TRACE ELEMENTS

A total of 32 elements were analyzed across H1 between 17.0 and 27 mm at a resolution of 13 μm (Fig. 3.4). Trace element profiles cover the time intervals from 134.9 ± 0.4 to 133.1 ± 0.7 (growth phase II) and 131.9 ± 0.6 to 131.5 ± 0.5 ka BP (growth phase I). Of these elements, only Mg, Sr, P, Al, Y, Ti and U were considered as their paleoclimatic and environmental significance is well characterized by numerous studies (Fairchild and Treble, 2009). The MF3 trace element profiles show pronounced changes in trace element concentrations between growth phases I and II (Fig. 3.4). Between 27.0 to 20.6 mm (growth phase II), Mg concentrations vary from 3538 to 10110 mg/kg, around a mean of 4907 mg/kg. Between 20.6 and 17.0 mm (growth phase I) Mg concentrations are lower and vary between 1946 and 3725 mg/kg around a mean of 2755 mg/kg. Sr concentration for growth interval I vary from 543 to 1208 mg/kg (mean 948 mg/kg), and from 333 to 818 mg/kg (mean 458 mg/kg) for growth interval. U concentrations vary from 6 to 30 mg/kg (mean 12 mg/kg) below, and from 2 to 11 mg/kg (mean 5 mg/kg) above H1. P concentrations vary from 29 to 598 mg/kg (mean 140 mg/kg) below, and from 110 to 717 mg/kg (mean 322 mg/kg) above H1. After H1, at 20.6 mm depth in the sample, concentration peaks in trace elements such as Al (from 0.5 to 1285 mg/kg), Ti (from 1 to 104 mg/kg) and Y (0.1 to 3.5 mg/kg) were determined. Moreover, the peaks in Al, Y and Ti above H1 correlate with a distinct positive shift in the $\delta^{18}\text{O}$ profile between 20.3 and 19.7 mm.

3.5. DISCUSSION

3.5.1. GROWTH PHASES

Growth phases of stalagmite MF3 can provide first information on the climatic conditions at the cave site since stalagmite growth is dependent on the availability of drip water. The inception of stalagmite growth in Schafslösch Cave at 137.4 ± 1.4 ka BP indicates the presence of drip water and cave air temperatures above 0°C (Fig. 3.3). This timing is in good agreement with the onset of speleothem deposition at 136.7 ± 2.8 ka BP in Spannagel Cave (2200-2500 m a.s.l) in Austria (Holzkämper et al., 2005). Such an early inception of speleothem growth in both alpine caves is most likely related to climate-induced switches from a cold- to a warm-based glacier above both caves (Holzkämper et al., 2005; Spötl et al., 2006; Spötl and Mangini, 2007; Fig. 3.5A, B) as a warm-based glacier can keep the cave temperature above 0°C and provide a drip water supply even if mean annual air temperatures at the surface are below the freezing point (Atkinson, 1983, Spötl et al., 2006). Though there is currently no direct geological evidence for the presence of a glacier above Schafslösch Cave as pre-Eemian glacial deposits in this area were eroded by subsequent glaciations, positive $\delta^{13}\text{C}$ values of around 6.5‰ are very similar to those values measured in contemporaneously deposited stalagmites from the slightly

Fig. 3.4. Trace element and stable isotope profiles for stalagmite MF3. Dashed red line denotes $\delta^{18}\text{O}$ values of actively growing stalagmites in Alpeel Cave. Dashed red lines with values denote mean $\delta^{18}\text{O}$ for growth phases II and I (see also Fig. 3 for further details). The vertical yellow bar denotes the hiatus 1.

higher elevated Spannagel Cave, which was also covered by a glacier at the beginning of the penultimate deglaciation (Spötl and Mangini, 2007).

The cessation of stalagmite growth between 133.1 ± 0.7 and 131.9 ± 0.6 ka BP is more difficult to explain and could be related to at least three factors: (1) a climate-induced change from a warm- to a cold-based glacier and subsequent cessation of water supply, (2) drop in cave air temperatures below 0°C due to ice free conditions and lack of an insulating effect of the ice above the cave, and (3) a temporary blocking of the fissure feeding stalagmite MF3 with water (Fig. 3.5C). The latter hypothesis appears to be rather unlikely considering the evidence from Spannagel Cave where the growth of several stalagmites also ceased at 133.0 ± 0.9 ka BP due to a cold spell and glacier re-advance (Spötl et al., 2006; Spötl and Mangini, 2007). Considering the elevation of Schafsfloch Cave (1890 a.s.l.) makes it rather unlikely that the area was ice-free at around 133.1 ± 0.7 ka BP. Rather, we suggest that the glacier above the Schafsfloch Cave changed its thermal state again from a cold- to a warm-based glacier (Fig. 3.5D). It is therefore more likely that the 1.2 ka-long hiatus (H1) in stalagmite MF3 is related to a return to colder and drier climatic conditions and decrease in seasonality (colder summers) (Spötl et al., 2006).

Growth of stalagmite MF3 resumed at 131.9 ± 0.6 ka BP and indicates a change from cold- to warm-based glacier and its subsequent retreat and an increase in MAAT above 0°C . The final cessation of MF3 stalagmite growth occurs at 130.1 ± 0.5 ka BP, whereas the ultimate cause for final cessation remains enigmatic.

Fig. 3.5. A-D Schematic model of the environmental conditions above Schafsfloch Cave during the penultimate deglaciation.

3.5.2. PALAEOCLIMATIC SIGNIFICANCE OF OXYGEN AND CARBON ISOTOPES

The oxygen isotopic composition of speleothems is primarily controlled by variations in $\delta^{18}\text{O}$ of the seepage water and precipitation above the cave, whereas fluctuations in $\delta^{18}\text{O}$ of precipitation are closely related to climatic changes (Lachniet, 2009).

A key-question is whether stalagmite MF3 covers T-II in full, as its growth stops already at 130.1 ± 0.5 ka BP (Fig. 3.3). At least two observations suggest that T-II is indeed captured by the MF3 record. First, $\delta^{18}\text{O}$ values (Fig. 3.4) of around -7.9 ‰ at around 130.1 ± 0.5 ka BP are close to modern calcite values of around -7.6 ‰ (-7.8 ‰ when the altitude effect of around 0.2 ‰ per 100 meters (Schürch et al., 2003) is taken into account) in the nearby Alpeel Cave (Alpstein Mts., 1774 m a.s.l.; Fig. 3.1), and also very close to Eemian $\delta^{18}\text{O}$ values of around -9 ‰ in stalagmites from Spannagel Cave (Holzkämper et al., 2004, 2005). Secondly, the increase of ~ 3.5 ‰ in the MF3 $\delta^{18}\text{O}$ record across the penultimate deglaciation is almost identical to the positive isotopic shift of around 3.0 ‰ in contemporaneously deposited speleothems from Spannagel Cave (Holzkämper et al., 2005; Spötl and Mangini, 2007). We therefore assume that T-II is almost fully covered by stalagmite MF3.

The positive shift of 3.5 ‰ in the MF3 $\delta^{18}\text{O}$ record (Fig. 3.4) can be related to several effects such as changes in (1) $\delta^{18}\text{O}$ of North Atlantic surface water (“ice volume effect”), (2) air mass trajectories (“moisture source effect”), (3) air temperature (“temperature effect”), (4) the seasonality of precipitation and (5) cave air temperature.

The 3.2 ‰ positive shift in $\delta^{18}\text{O}$ cannot be explained alone by a change in $\delta^{18}\text{O}$ of North Atlantic surface water. Assuming that seawater $\delta^{18}\text{O}$ decreases by 0.08 ± 0.02 ‰ per 10 meters of global sea level rise, the increase of ~ 120 m in global sea level (Fig. 3.6A) across T-II accounts for only a 1 ‰ negative shift in $\delta^{18}\text{O}$ seawater (Duplessy et al., 2007). The “ice volume effect” is therefore not responsible for the positive shift of around 3.2 ‰ in calcite $\delta^{18}\text{O}$. A significant change in the moisture source cannot be ruled out completely, but it is reasonable to assume that the Atlantic was the main vapor source throughout the penultimate deglaciation. Because $\delta^{18}\text{O}$ of modern precipitation in Switzerland is strongly governed by air temperature (Schürch et al., 2003; Kern et al., 2013), the distinct positive shift in the MF3 $\delta^{18}\text{O}$ profile is most likely related to an increase in air temperature above Schafsloch Cave. At present, the $\delta^{18}\text{O}$ -temperature relation ($d\delta^{18}\text{O}/dT$) at high alpine sites in Switzerland is around 0.7 ‰/°C, a value that is only slightly higher compared to 0.6 ‰/°C at lower elevated sites in Switzerland and central Europe (Rozanski et al., 1997; Schürch et al., 2003). This $\delta^{18}\text{O}/dT$ relationship could vary over time, which limits the use of MF3 $\delta^{18}\text{O}$ values for precise quantitative temperature reconstruction across T-II. A rough estimation, however, is possible. Taking the modern $d\delta^{18}\text{O}/dT$ relationship of 0.7 ‰, the temperature-dependent fraction of $\delta^{18}\text{O}$ during calcite precipitation ranging between $0.17 - 0.22$ ‰/°C; Kim and O’Neil, 1997; Tremaine et al., 2011) and the positive shift of ~ 1 ‰ in $\delta^{18}\text{O}$ of Atlantic surface water into account, the net isotopic shift of around 4.2 ‰ translates to an increase in mean annual air temperature of around 8.0 °C above Schafsloch Cave during the penultimate deglaciation. This glacial/interglacial temperature shift compares with other marine and terrestrial archives covering T-II, which provide evidence for a rapid increase of between 8° and 14.0 ± 2.7 °C in mean annual air temperature across T-II (Wainer et al., 2011; Brewer et al., 2008; Sanchez-Goni et al., 2012; Martrat et al., 2014). The small mismatch could indicate an additional influence of seasonal changes in precipitation and/or infiltration on $\delta^{18}\text{O}$ of cave drip water, an effect that has been also observed in a contemporaneously deposited stalagmite from Villars Cave (Wainer et al., 2011).

Speleothem calcite $\delta^{13}\text{C}$ values are sometimes difficult to interpret in terms of climatic and

environmental changes as they can be influenced by multiple factors acting within the soil zone, the karst aquifer and the cave system. The most decisive factors include changes in (1) the density and type of vegetation (proportion of C3 and C4 plants), (2) microbial processes in the soil zone, (3) recharge conditions (closed versus open system dissolution) and (4) CO₂ degassing. In general, $\delta^{13}\text{C}$ calcite values of -14 to -6‰ and -6 to +2‰ can be indicative of C3 and C4 vegetation respectively (McDermott, 2004; Frisia and Borsato, 2010). Soil microbial activity will be enhanced at higher temperatures and soil moisture, which would lead to lower $\delta^{13}\text{C}$ values in the stalagmite (McDermott, 2004; Spötl et al., 2005; Fleitmann et al., 2009; Rudzka et al., 2011). However, recharge conditions and equilibration of infiltrating water with soil CO₂ are additional parameters influencing $\delta^{13}\text{C}$ values in speleothems, particularly when soils are thin or absent above the cave. Finally, low drip rates and ventilation of the cave can lead to enhanced CO₂ degassing and thus elevated calcite $\delta^{13}\text{C}$ values (Baker et al., 1997; Mühlinghaus et al., 2009; Deininger et al., 2012). In high alpine caves, speleothems derived from pure atmospheric CO₂ source can be as heavy as +6 ‰ VPDB, with higher values indicating kinetic isotope fractionation (Spötl et al., 2004).

Stalagmite MF3 $\delta^{13}\text{C}$ values of around 6.5‰ between 137.4 ± 1.4 and 133.1 ± 0.7 ka BP indicate both a lack of soil-derived CO₂ in seepage water due to ice above Schafsloch Cave (Fig. 3.4). Thus, $\delta^{13}\text{C}$ values are primarily influenced by bedrock $\delta^{13}\text{C}$ of the Seewerkalk Formation (approx. +2‰; Wissler et al., 2003) and degassing effects due to very slow drip rates within Schafsloch Cave. MF3 $\delta^{13}\text{C}$ values decrease rapidly after 131.9 ± 0.6 ka BP until values of around -2‰ are reached at around 131.3 ± 0.8 ka BP, reflecting an increasing contribution of biogenic carbon as a result of soil and vegetation development above Schafsloch Cave. This assumption is also supported by our observations of growth phase I under UV-light, where content of organic matter appears to be generally higher compared to growth phase II (Fig. 3.2). It is also noteworthy that these $\delta^{13}\text{C}$ values are even more negative than those obtained from a present-day stalactite (-0.4‰ VPDB) from the nearby Alpeel Cave (Alpstein Mts., 45 m length, 1774 m alt., Fig. 3.1).

3.5.3. TRACE ELEMENTS

Trace elements can provide additional climatic and environmental information and, thus, complement stable isotope records. They are transported as particles, solutes or adsorbed onto colloids and incorporated in calcite according to their concentration in the drip water (Fairchild and Treble, 2009). For this study, Mg, Al, P, Ti, Sr, Y and U were used as they are well-established indicators for effective rainfall, groundwater residence time, soil processes, erosion and growth rate (Fairchild and McMillan, 2007; McDonald et al., 2004; Roberts et al., 1998; Zhou et al., 2005).

Higher concentrations of Mg and U are commonly interpreted to reflect longer residence times of water in the aquifer above the cave at times of lower effective recharge and precipitation respectively (Baldini et al., 2002; Hellstrom and McCulloch, 2000; McDonald et al., 2004). In addition, Mg and U contents are also related to prior calcite precipitation at times of low effective moisture (Fairchild and McMillan, 2007; Drysdale et al., 2009). Treble et al., (2003) suggest that fluctuations in Sr are related to changes in stalagmite growth rate and soil processes, whereas P is often used as an indicator for soil and vegetation productivity linked to both temperature and precipitation changes (Borsato et al., 2007; Fairchild et al., 2001; Treble et al., 2003). Rare earth elements, such as Y and Ti, are not frequently used, but they are considered to be indicators for enhanced weathering of the overlying soil and host rock during wetter climatic conditions (Richter et al., 2004; Zhou et al., 2008). Y can be used as a tracer for detrital (including colloidal) transport and rainfall proxy (Schimpf et al., 2011, whereas concentrations

of Ti can vary in concert with detritus content due to its extremely low solubility (Fairchild and Baker, 2012). Another element that is typically incorporated in the fine-grained detrital layers deposited on speleothems during flooding events is Al (Borsato et al., 2007). Ti, Y and Al are thus common in so-called “impulse laminae”, which are formed during high infiltration events and associated enhanced mobilization of colloids and particles from soils and debris above Schafsloch Cave (Fairchild and Treble, 2009; Fairchild and Baker, 2012).

Varying trace element concentrations in stalagmite MF3 are therefore additional proxies for changes in precipitation and groundwater residence time (Mg, U), growth rate (Sr), soil processes (P) and input of detrital material (Ti, Y, Al) (Fig. 3.4). The abrupt decrease in U and Mg concentrations immediately after 131.9 ± 0.6 ka BP and their low contents (compared to growth phase II between 137.4 ± 1.4 and 133.1 ± 0.7 ka BP) is strong evidence for higher precipitation and shorter groundwater residence times. The inverse correlation between the U and P profiles supports our interpretation that U concentrations are related to bedrock dissolution processes. The distinct and short-lived peaks in Ti, Y and Al at the beginning of growth phase I (Fig. 3.4) clearly exceeding background variability and are most likely related to erosion of glacial debris and high infiltration of water (lower Mg and U concentrations), supporting our assumption that the glacier covered Schafsloch Cave until 133.1 ± 0.5 ka BP. The higher P content during growth phase I ($131.9 \pm 0.6 - 130.1 \pm 0.5$ ka BP) is related to climatic amelioration and development of soil and vegetation above the cave. Overall, the observed trace element pattern supports our interpretation of a rapid disintegration of the glacier above Schafsloch Cave and a significant increase in temperature and precipitation immediately after 131.9 ± 0.6 ka BP.

3.5.4. TIMING OF THE PENULTIMATE DEGLACIATION

The precise chronology and high temporal resolution of the stalagmite MF3 isotope (~ 20 yr resolution) and trace element (< 1 yr resolution) records allows us to study the inception and progression of the penultimate deglaciation in the Swiss Alps, and to compare the timing of the midpoint of T-II in the Swiss Alps with other absolutely dated stalagmite records.

Fig. 3.6. Comparison of the Schafsloch $\delta^{18}O$ profile (red curves in A-C) with (A) smoothed global sea level (Grant et al., 2012; blue shaded area denotes the 95% confidence intervals), (B) carbon dioxide concentration in ice cores from Antarctic (Schneider et al., 2012), and (C) summer insolation (July) at 65°N (Berger and Loutre, 1992).

Fig. 3.7. Comparison of palaeoclimate records covering the penultimate deglaciation. **A** Mixed oak forest and **B** pollen-based summer temperature reconstructions in core MD-04-2845 (Goni et al., 2012). **C** Schafsloch Cave Mg record and **D** $\delta^{18}\text{O}$ record. The yellow vertical bar denotes the hiatus 1 in the stalagmite MF3. **E** $\delta^{18}\text{O}$ record from Sofular Cave (Badertscher et al., 2011). **F** $\delta^{18}\text{O}$ Ostracod record from the Black Sea (22GC-8; Wegwerth et al., 2014). **G** Record of ice rafted debris (IRD) in core 22GC-8. **H** Strontium isotope record derived from the Black Sea. The blue bars denote Black Sea water pulses (BSWP) as identified by Wegwerth et al., 2014. **I** Core 22GC-8 Sr/Ca record. **J** Sanbao and Dongge Cave $\delta^{18}\text{O}$ record from China (Kelly et al., 2006; Cheng et al., 2009), WMI-II denotes the weak monsoon interval. **K** The North Atlantic record of ice rafted debris (IRD) (McManus et al., 1999). The age model is based on tuning the IRD record to the Sanbao Cave record, further details are provided by Cheng et al., 2009.

At Schafsloch Cave the penultimate deglaciation started at 137.4 ± 1.4 ka BP with a change from a cold- to warm-based glacier when summer temperatures rose above 0°C (modern mean summer temperature at Schafsloch Cave is 8.5°C). This change occurs at a time of low but rising northern hemisphere summer insolation (Fig. 3.6C), and is within age uncertainties also in phase with increasing atmospheric carbon dioxide concentrations in ice cores from East Antarctica (EDC and Talos dome ice cores; Schneider et al., 2013; Fig. 3.6B) and rising global sea level (Grant et al., 2012; Fig. 3.6A). Furthermore, the start of the penultimate deglaciation in the Alps at around 137.4 ± 1.4 ka BP is concurrent with the onset of stalagmite growth in Spannagel Cave at 136.7 ± 2.8 ka BP and in southwestern Oregon (Oregon Caves National Monument; Ersek et al., 2009) at 135.0 ± 1.2 ka BP, and also the beginning retreat of the Laurentide and Scandinavian ice sheets at around $\sim 140 \pm 3$ ka BP (Wood et al., 2010; Larsen et al., 2009).

The growth cessation of stalagmite MF3 between 133.1 ± 0.7 and 131.9 ± 0.6 ka BP was most likely triggered by a cold spell and an associated change in the thermal state of the glacier (from warm- to cold-based) above Schafsloch Cave (Fig. 3.5C). The timing of this cold episode is in good agreement with the cessation of speleothem growth in Spannagel Cave at around 133 ka BP (Spötl et al., 2006), and appears to be also a feature of stalagmite records from Norway, Spain and France (Lauritzen, 1995; Spötl et al., 2006; Hodge et al., 2008; Genty et al., 2013), albeit chronologies of these records suffer from large (>2 ka BP) chronological uncertainties and age reversals. This cold-spell in the Alps could be related to the “T-II pause” (Gouzy et al., 2004) or a Younger Dryas-type event. Interestingly, a cold anomaly, centered at 131.4 ± 2 ka BP, is also evident in the pollen-derived temperature reconstruction in sediment core MD04-2845 (Goni et al., 2012; Fig. 3.7A, B). Furthermore, this cold spell occurs at a time of rapidly rising sea level (Fig. 3.6A), very weak East Asian Monsoon (EAM) intensity (Fig. 3.7J) and coincides also with Heinrich event 11, suggesting that the cold spell in the Alps might have been triggered by a weakening of the Atlantic Meridional Ocean Circulation (AMOC) due to an increased influx of meltwater and icebergs into the North Atlantic (e.g., Cheng et al., 2009). However, we must emphasize that evidence for a comparable cold event is missing in numerous other records, including in the stalagmite records from Corchia and Nevada Caves (Fig. 3.8D-F). Clearly, further research is required to fully explore the amplitude and spatial extent of this cold anomaly in closer detail.

The recommencement of stalagmite deposition at 131.9 ± 0.6 ka BP coincides with the disintegration of the glacier above Schafsloch Cave within several decades or centuries, as evidenced by a sudden positive shift in $\delta^{18}\text{O}$, rapidly decreasing $\delta^{13}\text{C}$ values due to an rising contribution of organic carbon, and very distinct spikes in Ti, Al and Y as a result of enhanced inflow of debris by the melting ice (Fig. 3.4). Furthermore, increased precipitation, higher infiltration and shorter groundwater residence times are indicated by a rapid decrease in Mg and U concentrations. The rapid disintegration of the glacier covering Schafsloch Cave is concurrent with a stepwise increase in pollen-derived summer temperatures and mixed oak forest in sediment core MD04-2845 from the European margin at (Goni et al., 2012; Fig. 3.7A, B). This is not surprising since summer temperatures are the key factor for the mass balance of glaciers in the Alps (e.g., Huss et al., 2010). It is noteworthy that stalagmite growth started later in Spannagel Cave at around 129.9 ± 0.9 ka BP, which is probably related to the higher elevation of Spannagel Cave (2250-2500 m asl) compared to Schafsloch Cave (1890 m asl). Almost full interglacial conditions were reached at around 130.3 ± 0.3 ka BP, when MF3 $\delta^{18}\text{O}$ calcite values are almost identical to those recorded in modern stalagmites in the nearby Alpeel Cave, and very similar to $\delta^{18}\text{O}$ values of -9‰ in Eemian speleothems from Spannagel Cave (Holzkämper et al., 2004). Taking the half-height

Fig. 3.9. Comparison of the stalagmite MF3 $\delta^{18}\text{O}$ -profile (A-F) with other ^{230}Th -dated stalagmite records covering the penultimate deglaciation. **A** Sofular Cave (Badertscher et al., 2011), **B** Dongge and Sanbao Cave (Kelly et al., 2006; Cheng et al., 2009), **C** Soreq Cave (Grant et al., 2012), **D** Corchia Cave (Drysdale et al., 2009), **E** Tan ache Urla Cave (Regattieri et al., 2014), **F** Nevada Caves (Shakun et al., 2011; Lachniet et al., 2014). The green vertical bars denote the timing of the midpoint of T-II in stalagmites from Schafsloch, Corchia, Tan ache Urla and Nevada Caves (T-II) and Sanbao Cave (T-II*)

increase of MF3 $\delta^{18}\text{O}$ values of around -9.9‰ (Fig. 3.4), the timing of the mid-point of T-II should be placed at around 131.8 ± 0.6 ka BP. This date is in excellent agreement with independently derived age estimates for the midpoint of T-II of 131.8 ± 0.6 ka BP in precisely-dated stalagmites from Nevada (Shakun et al., 2011; Lachniet et al., 2014; Fig. 3.8F) and 132.1 ± 1.8 ka BP in stalagmites from Corchia Cave and Tan ache Urla Cave, Italy (Drysdale et al., 2009; Regattieri et al., 2014; Fig. 3.8D, E). Furthermore, the $\delta^{18}\text{O}$ profiles of all stalagmites are remarkably similar during the entire penultimate deglaciation, whereas the Nevada Cave composite $\delta^{18}\text{O}$ record is also governed by temperature changes in the Great Basin (Shakun et al., 2011; Lachniet et al., 2014). In contrast to Schafsloch and Nevada Caves, variations in $\delta^{18}\text{O}$ in the Corchia and Tan ache Urla Cave records are primarily driven by fluctuations in the amount of precipitation (the so-called “amount effect”) driven by changes in sea surface temperatures (SST) in the Atlantic and Mediterranean. Because temperatures in the Swiss Alps are strongly influenced by SSTs in the Atlantic (e.g., Huss et al., 2010), a close relationship between the Corchia, Tan ache Urla and Schafsloch $\delta^{18}\text{O}$ records can be expected. Taken these evidences together, the temperature-controlled $\delta^{18}\text{O}$ stalagmite records from Nevada, Switzerland and Italy place the midpoint of T-II close to 132 ka BP. This age, however, is not concurrent with the one in precisely-dated stalagmite $\delta^{18}\text{O}$ records from Sanbao Cave (Cheng et al., 2009), Dongge Cave (Kelly et al., 2005), Soreq Cave (Grant et al., 2012) and Sofular Cave (Badertscher et al., 2011). All of these records suggest a much younger age for the midpoint of T-II. The most precise age estimate is provided by the Sanbao Cave record from China, which places the midpoint of T-II at 129.1 ± 0.1 ka BP, and thus 2.8 ± 0.7 ka later compared to the precisely-dated Schafsloch and the Nevada, Tan ache Urla and Corchia cave records. Given the integrity of the ^{230}Th -dating of the Sanbao, Sofular and Schafsloch Cave stalagmites (and all other stalagmites shown in Fig. 3.8), both samples were dated in the same laboratory at the University Minnesota, the age offset cannot be explained by methodological or analytical artefacts. The phase lag between Sanbao Cave (and also Sofular and Soreq Caves) and Schafsloch Cave (and also Corchia and Nevada Caves) is indeed real.

Two further records, Soreq and Sofular Cave (Fig. 3.8A, C), are of limited use for determining the timing of the midpoint of T-II as their $\delta^{18}\text{O}$ calcite values are primarily influenced by changes in $\delta^{18}\text{O}$ of sea surface waters in the Mediterranean and Black Sea (the so-called “source effect”; Bar-Matthews et al., 2003; Fleitmann et al., 2009; Badertscher et al., 2011). Because seawater $\delta^{18}\text{O}$ values of both seas are strongly driven by riverine influx from the Nile and from the Danube/Dniester/Dnieper into the Eastern Mediterranean basin and the Black Sea respectively (particularly when the Black Sea was landlocked; Badertscher et al., 2011), both the Soreq and Sofular $\delta^{18}\text{O}$ records are not direct recorders of precipitation and temperature. However, the Soreq Cave $\delta^{18}\text{O}$ record holds some information on the strength African monsoonal rainfall in the highlands of Ethiopia, the headwaters of the Blue Nile. The abrupt negative shift shortly after 129 ka BP in the Soreq Cave $\delta^{18}\text{O}$ profile reveals a stepwise intensification of the African monsoon and is herefore in very good agreement with the abrupt increase in EAM intensity at 129.1 ± 0.1 ka BP in China.

The different ages between the mid-points of T-II between absolutely-dated stalagmite records appear to be puzzling and there is an apparent systematic age offset between mid-latitudinal and low-latitudinal stalagmite records. However, we propose that this offset can be best explained by the competing effects of insolation forcing and glacial boundary forcing on the intensity of the EAM (and also African monsoon) during the penultimate deglaciation. A detailed comparison between the Schafsloch, Sofular, Sanbao Cave $\delta^{18}\text{O}$ records and a Black Sea sediment trace element, Sr isotope and IRD record (core 22GC-8; Wegwerth et al., 2014) helps to shed further light on the mechanisms

leading to the delayed and very abrupt response of the EAM. Figure 8 clearly reveals that the transition towards warmer /wetter conditions in Europe and North America occurs during a weak (dry) phase of the EAM, as indicated by high $\delta^{18}\text{O}$ values between 135.5 ± 1.0 to 129.1 ± 0.1 ka BP (the so-called “weak monsoon interval” WMI II; Fig. 3.7J) in the Sanbao $\delta^{18}\text{O}$ profile (Cheng et al., 2009; Cheng et al., 2006). An abrupt shift of 4‰ in $\delta^{18}\text{O}$ at 129.0 ± 0.1 ka BP marks the fast transition into full interglacial conditions and a strong EAM in China (Cheng et al., 2009). The lagged and abrupt response of the EAM has been attributed to cold winter temperature anomalies in the North Atlantic during the WMI II (Cheng et al., 2009), which were probably caused by a weakening of the Atlantic meridional overturning circulation (AMOC) and reduced surface-ocean heat flux to the North Atlantic as a result of a high influx of meltwater and icebergs (as evidenced by ice rafted debris during Heinrich event 11; Fig. 3.7K) from the rapidly disintegrating ice-sheets. This cold anomaly would have been even amplified by a greater extent of sea-ice, causing longer and more severe winters between 135.5 ± 1.0 to 128.9 ± 0.1 ka BP (Cheng et al., 2009), and also greater snow cover extent in Eurasia. Evidence for extremely cold winters in Eurasia is provided by a record (core 22GC-8) of ice rafted debris (IRD) from the Black Sea (Nowaczyk et al., 2013; Shumilovskikh et al., 2013; Wegwerth et al., 2014; Fig. 3.7G), whereas the uncertainties of this record are around 0.7 ka as its chronology is based on the correlation between the 22GC-8 $\delta^{18}\text{O}_{\text{ostracod}}$ and the precisely dated Sofular So-6 $\delta^{18}\text{O}_{\text{calcite}}$ records (see Shumilovskikh et al., 2013 for further details on the chronology of core 22GC-8). The presence of IRD in the 22GC-8 IRD shows that strong winters in Eurasia with extended sea ice in the Black persisted at least until 129.9 ± 0.7 ka BP (Wegwerth et al., 2014), a timing that is in almost perfect agreement with the abrupt increase of EAM intensity at around 129.0 ± 0.1 ka BP in the Sanbao Cave record. Furthermore, both the Sofular and the 22GC IRD records reveal at least two prolonged pulses of meltwater discharge from the disintegrating ice sheets in Eurasia between 133.5 and 132.5 (BSWP-II-1) and 131.5 and 130.5 ka BP (BSWP-II-2) into the Black Sea (Badertscher et al., 2011; Wegwerth et al., 2014; Fig. 3.7E, H, J). Based on Sr-isotope signatures in ostracod shells, Wegwerth et al. (2014) suggest that BSWP-II-2 originated partly from the western Himalaya and entered the Black Sea from the Caspian Sea through the Manych depression (see also Badertscher et al., 2011 for detailed discussion on meltwater routing), providing direct evidence that larger ice sheets persisted at least until 130.5 ± 0.7 ka in Eurasia. Considering these evidences, the persistence of IRD in the Black Sea until 129.9 ± 0.7 ka BP and occurrence of BSWP-II-2 between 131.5 ± 0.7 and 130.5 ± 0.7 ka BP (Fig. 3.7G-I), supports the assumption that cold winters, enhanced snow cover as well as the remaining ice sheets in Eurasia suppressed Asian monsoon intensity until at least 129.9 ± 0.7 ka BP. We thus support the notion that the Asian monsoon and ITCZ responds largely to wintertime cold anomalies in the North Atlantic and Eurasia (e.g., Barnett et al., 1988; Denton et al., 2005; Cheng et al., 2009; Fleitmann et al., 2008), as suggested by Denton et al. (2005): “winter is the common link between Greenland-European temperatures, the Atlantic ITCZ and Asian Monsoons”. This is not in contradiction to rising temperatures documented by the Schafslösch, Corchia and Nevada Cave $\delta^{18}\text{O}$ records, which can be attributed to insolation-driven increases in summer temperatures. While rising summer temperatures since around 137 ka BP triggered the melting of the glaciers during the penultimate deglaciation, the resultant increased influx of meltwater weakened the AMOC caused colder winter temperatures until at least 129.9 ± 0.7 ka BP. The resultant greater extent of Eurasian snow cover outweighed rising summer insolation and locked the EAM in a weak mode as shown by the Sanbao Cave $\delta^{18}\text{O}$ record.

3.6. CONCLUSIONS

High-precision ^{230}Th – dating reveals that stalagmite MF3 was deposited between 137.4 ± 1.4 ka BP and 133.1 ± 0.7 ka BP, and 131.9 ± 0.6 ka BP and 130.1 ± 0.5 ka BP. The onset of the stalagmite growth at 137.4 ± 1.4 ka BP was triggered by a switch in the thermal state of the glacier (from cold- to warm-based) overlying the cave, as a result of increasing summer insolation and temperatures, respectively. The change from warm to cold-based led to a rise in cave air temperature above 0°C and allowed the water to enter the cave. However, $\delta^{13}\text{C}$ values of around 6.5 ‰ until 131.9 ± 0.6 ka BP indicate a lack of soil-derived CO_2 , as the cave was still covered by a glacier. It is therefore most likely that the cessation of stalagmite growth between 133.1 ± 0.7 and 131.9 ± 0.6 ka BP was caused by a distinct temperature drop and associated change from warm to cold-based glacier during Heinrich event 11. Rapidly increasing $\delta^{18}\text{O}$ values after 131.9 ± 0.6 ka BP indicate a rapid warming and a melting of the glacier within a few decades, an observation that is also supported by rapidly decreasing $\delta^{13}\text{C}$ values and distinct peaks in Y, Ti and Al. Almost full interglacial conditions were reached at around 130.3 ± 0.3 ka BP when calcite $\delta^{18}\text{O}$ values of around -8.3 ‰ are comparable with those measured in modern calcite precipitated in the nearby Alpeel Cave. Based on the MF3 $\delta^{18}\text{O}$ profile we place the timing of the mid-point of T-II at around 131.8 ± 0.6 ka BP, which is in good agreement with precisely-dated records from North America and Europe. Such as early timing of T-II, however, is 2.8 ± 0.7 ka earlier than that recorded in the Sanbao Cave monsoon record from China, which places T-II in the Asian monsoon region at 129.0 ± 0.1 ka BP. The delayed response of the Sanbao Cave monsoon record is related to colder winter temperature anomalies and greater extent of Euroasian snow cover, which is confirmed by high ice drifted debris in the Black Sea sediments until 129.9 ± 0.7 ka BP. This confirms that the Asian monsoon and latitudinal position of the ICTZ during the penultimate deglaciation were strongly influenced by wintertime cold anomalies in the North Atlantic and Euroasia.

4.1. INTRODUCTION

Despite the last deglaciation being one of the most studied climatic intervals, numerous questions still remain with respect to its timing across the North Atlantic region, as regional impact and amplitude of the recorded proxy signals.

The present study focuses on the ultra-high resolution regional fluctuations during the Bölling-Allerød (B/A) and Younger Dryas (YD) in three coeval stalagmites from Milandre Cave in Switzerland. By replication of the isotopic time series in coeval stalagmites from the same cave we achieved the best confidence for this new data-set (Lachniet, 2009, Fohlmeister, 2012). Previous studies confirmed that stable isotopes in speleothems from Milandre Cave capture local and regional climatic fluctuations (Schmassmann, 2010, Hasenfratz, 2012, Affolter et al, 2015). A good understanding of the factors controlling the isotopic composition in the speleothems from Milandre Cave was achieved through monitoring studies in the cave (Affolter et al., submitted in revised form) and a strong correlation between calcite oxygen isotope ($\delta^{18}\text{O}$) values and surface temperature between 1700 and 1950 AD (Hasenfratz et al., in prep.). Calcite $\delta^{18}\text{O}$ values of speleothems in Milandre Cave therefore reflect long-term evolution (millennial-scale) of mean annual temperature with a bias toward the cold season, conditions similar to the ones described for Bunker Cave site, Germany (Fohlmeister, 2012).

The purpose of this study is three-fold: i) to reconstruct regional climate-induced environmental changes during the B/A and YD, independently dated and at a high-resolution scale, ii) to confirm the $\delta^{18}\text{O}/^{\circ}\text{C}$ transfer function calculated by Hasenfratz et al. (in prep.) by using different independent approaches (calcite $\delta^{18}\text{O}$, $\delta^{18}\text{O}$ and δD in fluid inclusions, and noble gasses in fluid inclusions), and iii) to obtain absolute annual-decadal temperature changes at the surface of the cave using the calculated transfer function.

4.2. SITE AND SAMPLE DESCRIPTION

Milandre Cave, is located in the Ajoie region of the Swiss Jura Mountains ($47^{\circ}49'\text{N}/ 7^{\circ}02'\text{E}$, 400 masl, Fig. 4.1), which represent the first significant orographic boundary for the moist and mild maritime air originating from the North Atlantic Ocean. Precipitation is therefore strongly controlled by westerly propagated air masses. The Eastern part of the Jura Mountains is almost completely shielded from a Mediterranean influence, with the Swiss Alps acting as a weather divide (MeteoSchweiz; Veit, 2002). The Alpine barrier is most efficient during winter, while during summer the Mediterranean moisture sources shift their position with about 14° northerly latitude and are able to contribute to the total local moisture budget by up to about $17.3 \pm 5.7\%$ (Sodemann and Zauber, 2011). Precipitation and temperature is measured at the nearby Fahy meteorological station ($47^{\circ}42'\text{N}/ 6^{\circ}94'\text{E}$, 596 masl, 200 m higher than our cave site) which is operated by the Swiss Federal Office of Meteorology and Climatology (MeteoSchweiz). For the interval 1961-1990 mean annual precipitation rate is 1037 mm/year and mean annual air temperature (MAAT) 8.1°C . The values changed for the 1990-2012 interval, with increased values of 1077 mm/year, and MAAT 9.2°C (Fig. 4.1). Of importance for our study is mean autumn to spring temperature (October-May) of 5.7°C , and the mean summer temperature (JJA) of 17.1°C . Precipitation is relatively equal over the year; with precipitation averaging 292 mm in summer and 224 mm in winter. Snowfall may occur from November to March, although this region exhibits a mild climate during winter (mean temperature above 0°C , MeteoSchweiz).

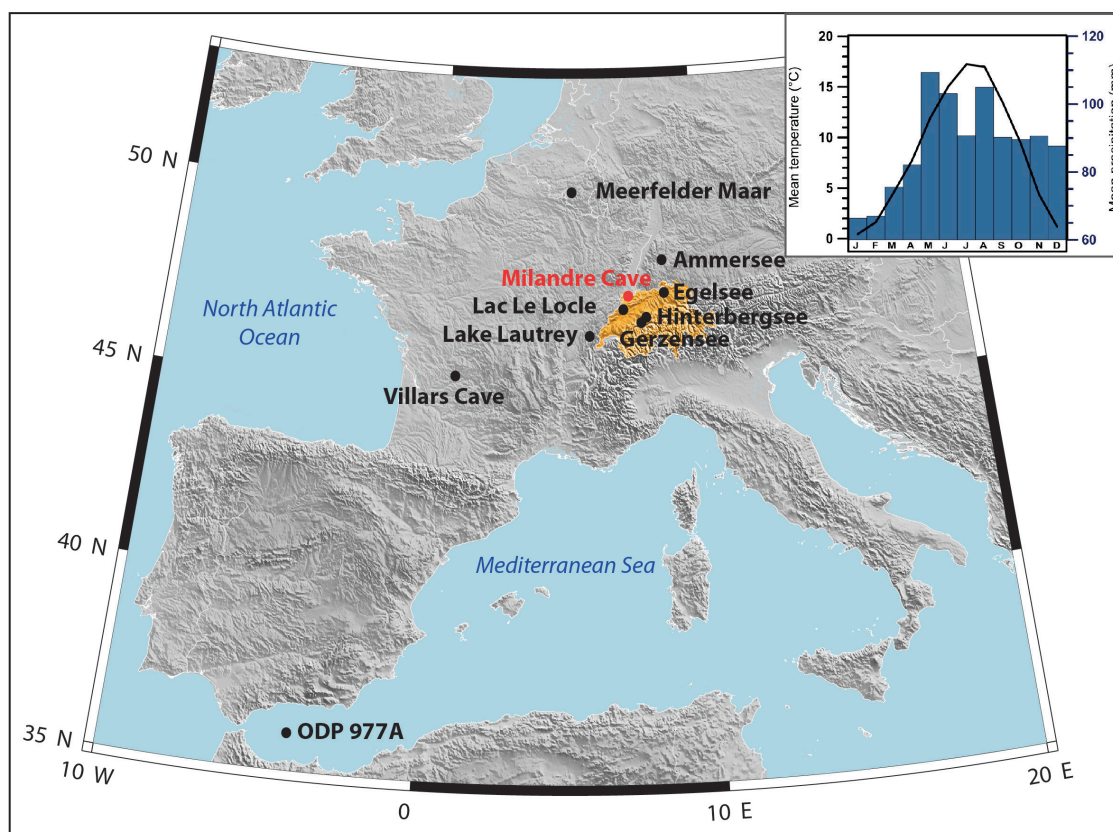

Figure 4.1. Location of the Milandre Cave and the other sites mentioned in the text. Right corner: Monthly averages of temperature and precipitation measured at Fahy meteorological station (near Milandre Cave).

Milandre Cave was developed in the limestone of the St.-Ursanne Formation, only 30-80 m below the surface. Nowadays, the bedrock is covered by less than 60 cm of soil, and a cardamine beech forest has developed above the cave. The cave is on two levels, with the lower level developing around 30 m below a fossil gallery. The lower level is active and used by the underground Milandrine River. Three stalagmites (M2, M6, M8) were collected from the Galerie des Fistuleuses, the upper level of the cave, about 450-500 m from the natural entrance. The temperature in this gallery is $9.8 \pm 0.2^\circ\text{C}$ (Affolter et al., submitted in revised form), with < 100 l/s air flow, humidity 100% and pCO_2 from 0.3 to 1.41 % (continuous and punctual measurements from 2008 to 2014). Occasionally, the pCO_2 concentration in the gallery can rise up to values around 4%, especially during late autumn and early spring, and the cause of this remains under investigation (pers.comm. Ph. Häuselmann, SISKa).

The sample locations in the gallery are shown by Fig. 4.2. The stalagmites M6 and M8 grew only several centimeters distance from each other, and in a distance of around 50 m from M2. Their growing location is less exposed to changes in ventilation and water flooding, due to a rather lateral and elevated position within the gallery compared to stalagmite M2.

All samples are composed of compact columnar calcite, and annual laminations are visible macroscopically and/or microscopically on the entire length of the samples. M2 was active when collected in 2008, and it was fed by a soda straw dripping at $5'10''$ - $6'20''$ time intervals (Schmassmann, 2010). The sample grew on the top of a clay deposit, in an area of the gallery exposed to changes in atmosphere and hydrology in the cave. M2 is a 25.6 cm long stalagmite, with a fairly constant diameter of 6-7 cm. Several clay layers in the upper 14 cm of the sample indicate flooding events in the cave. In

this paper we will refer only to the basal 15.1 – 25.6 cm of the sample (Fig. 4.3), where no flood layers are visible. Alternations of irregular laminae of white - porous and darker-compact calcite are present at 16 - 22 cm depth in sample. M6 and M8 grew on the same calcite base (Marine Isotope Stage 5 calcite, author pers. data), and a well-defined corrosion laminae marks the hiatus between the two calcite generations. Sample M6 is a 145.2 cm long stalagmite, and was active when collected in autumn 2011. The sample was fed by a soda straw dripping at 0'15'' - 6'00'' time intervals (Affolter et al., submitted in revised form). In this paper we will refer only to the basal 118 – 145.2 cm of the M6 sample (Fig. 4.3). Axial pores are observed in this section of the samples, with laminations observed between the rims of the pores. Sample M8 is a 13.25 cm long stalagmite, with a diameter of 8-10 cm. The sample was not active when collected in 2012. In this paper we will refer only at the basal 6.4–13.25 cm of the sample. The presence of white porous calcite between 7 to 8.2 cm depth and a change in the growth axis at 8.5 cm were observed (Fig. 4.3)

Figure 4.2. Map of Milandre cave (modified from Gigon and Wenger, 1986) and location of the samples in the cave (red dots). Bottom: Samples M6 and M8 and M2 before sampling. (photos: S.Schmassmann and A.D. Häuselmann)

4.3. METHODS

For Uranium-series dating (^{230}Th hereinafter), approximately 200 mg of powder was drilled along discrete growth horizons (Fig. 4.3). The ^{230}Th ages were determined on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS, Thermo-Finnigan Neptune) at the Department of Earth Sciences, University of Minnesota. Details of the methods, including standards used for mass fractionation and yield correction can be found in Cheng et al. (2013). The ^{230}Th dates of all samples are listed in the Table 4.1. An additional age for sample M2 is reported by Schmassmann (2010), $14\,304 \pm$

343 y BP at 24.5 cm depth in the sample, respectively. The samples $^{230}\text{Th}/^{232}\text{Th}$ ratio ranges between 89 -1092 atomic $\cdot 10^{-6}$ and have a U concentration of 63-430 ppb. All ages are quoted as years before 1950 (BP=1950).

Figure 4.3. Polished sections of M2 (upper left), M6 (upper right) and M8 showing micromilling paths for isotopic analysis (red lines), paths of trace elements analysis (orange lines), sampling locations for ^{230}Th calcite dating (black dots) and dating results. Blue sections approximate the location in samples of calcite precipitated during the Younger Dryas event.

A total of 930 samples were micromilled continuously at 0.2 mm and 0.5 mm increments. About 150-200 µg of powdered sample was placed in 12 ml vacutainers, flushed with He, and reacted with 5 drops of 99 % P₅O₅ at 70°C for 80 minutes. The samples were measured using a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. Results are reported relative to the international Vienna Peedee Belemnite (VPDB) standard. The analytical reproducibility based on repeated measurement of the internal standard for δ¹⁸O and δ¹³C is lower than 0.07 and 0.06 ‰ VPDB (1σ).

Laser ablation analyses were carried out in the Department of Chemistry and Applied Biosciences, Laboratory of Inorganic Chemistry, ETH Zürich. We used a 193 nm ArF excimer laser (GeoLas Pro, Lambda Physik) coupled to a quadrupole ICP-MS (ELAN 6100 DRC+, Perkin Elmer). A detailed description of the experimental setup is given in Kovacs et al. (2010) and optimized as described in Tabersky et al. (2013).

Noble gases in fluid inclusions (NG) were measured at the Department of Water Resources and Drinking Water, Eawag, using a recently developed combined vacuum crushing and sieving (CVCS) system'. The setup and operation conditions are described in Vogel et al. (2013). Absolute cave air temperature estimates are reconstructed using Ar, Kr, and Xe concentration extracted from the calcite water inclusions, with an uncertainty of up to ±2°C.

δ¹⁸O and δD of speleothem fluid inclusions were measured using a wavelength scanned cavity ring down spectroscopy (WS-CRDS) instrument, following the set up and procedure described in Affolter et al., 2014. For water released by the stalagmite calcite samples 0.5 µl, the standard deviation of isotope measurements is smaller than 1.5 ‰ for δD over a range of 0 and -210 ‰ at least and 0.4 ‰ for δ¹⁸O over a range of 0 and -27 ‰. Temperature estimates were obtained using the formula of Tremaine et al. 2011 (these compare most closely with modern conditions in the cave), and the uncertainty of the temperature reconstructions related to analytical error is around 0.9°C (Affolter et al., 2014).

4.4. RESULTS AND DISCUSSION

4.4.1. CHRONOLOGY

Age models were built for each sample using the COPRA algorithm (Breitenbach et al., 2012). Figure 4.4 shows the individual age-depth models for all three stalagmites and indicates that the samples were deposited between 11 000 and 14 560 years BP (BP=1950). The isotopic profiles for the samples are presented in Fig. 4.5 (upper part) and Fig. 4.6. Based on the assumption that climatic changes above the cave should be recorded simultaneously by each sample, we align distinct shifts in δ¹⁸O (Fig. 4.5) to the most reliable dated record (in terms of dated subsamples and dating precision), which is sample M8. A new chronology for samples M2 and M6 was therefore established by applying an eye-fit “event stratigraphy” in order to correlate the isotopic records (both δ¹⁸O and δ¹³C) to the M8 isotopic chronology (Fig. 4.4, 4.5 and 4.6), while the tuning was done within the error intervals of each record. Detailed information regarding the position of the fix points in each speleothem, age and error of the individual fix points (based on M8 chronology) are listed in Table 4.2.

To each fix point we attributed its corresponding 2 σ error given by the M8 COPRA chronology. This approach will account both for the error within M8 chronology and for the one introduced by the temporal resolution of our records (14 years for M2, and 7 years for M6, 25 years for M8). Fig. 4.4 shows the new calculated age-models for the samples M2 and M6.

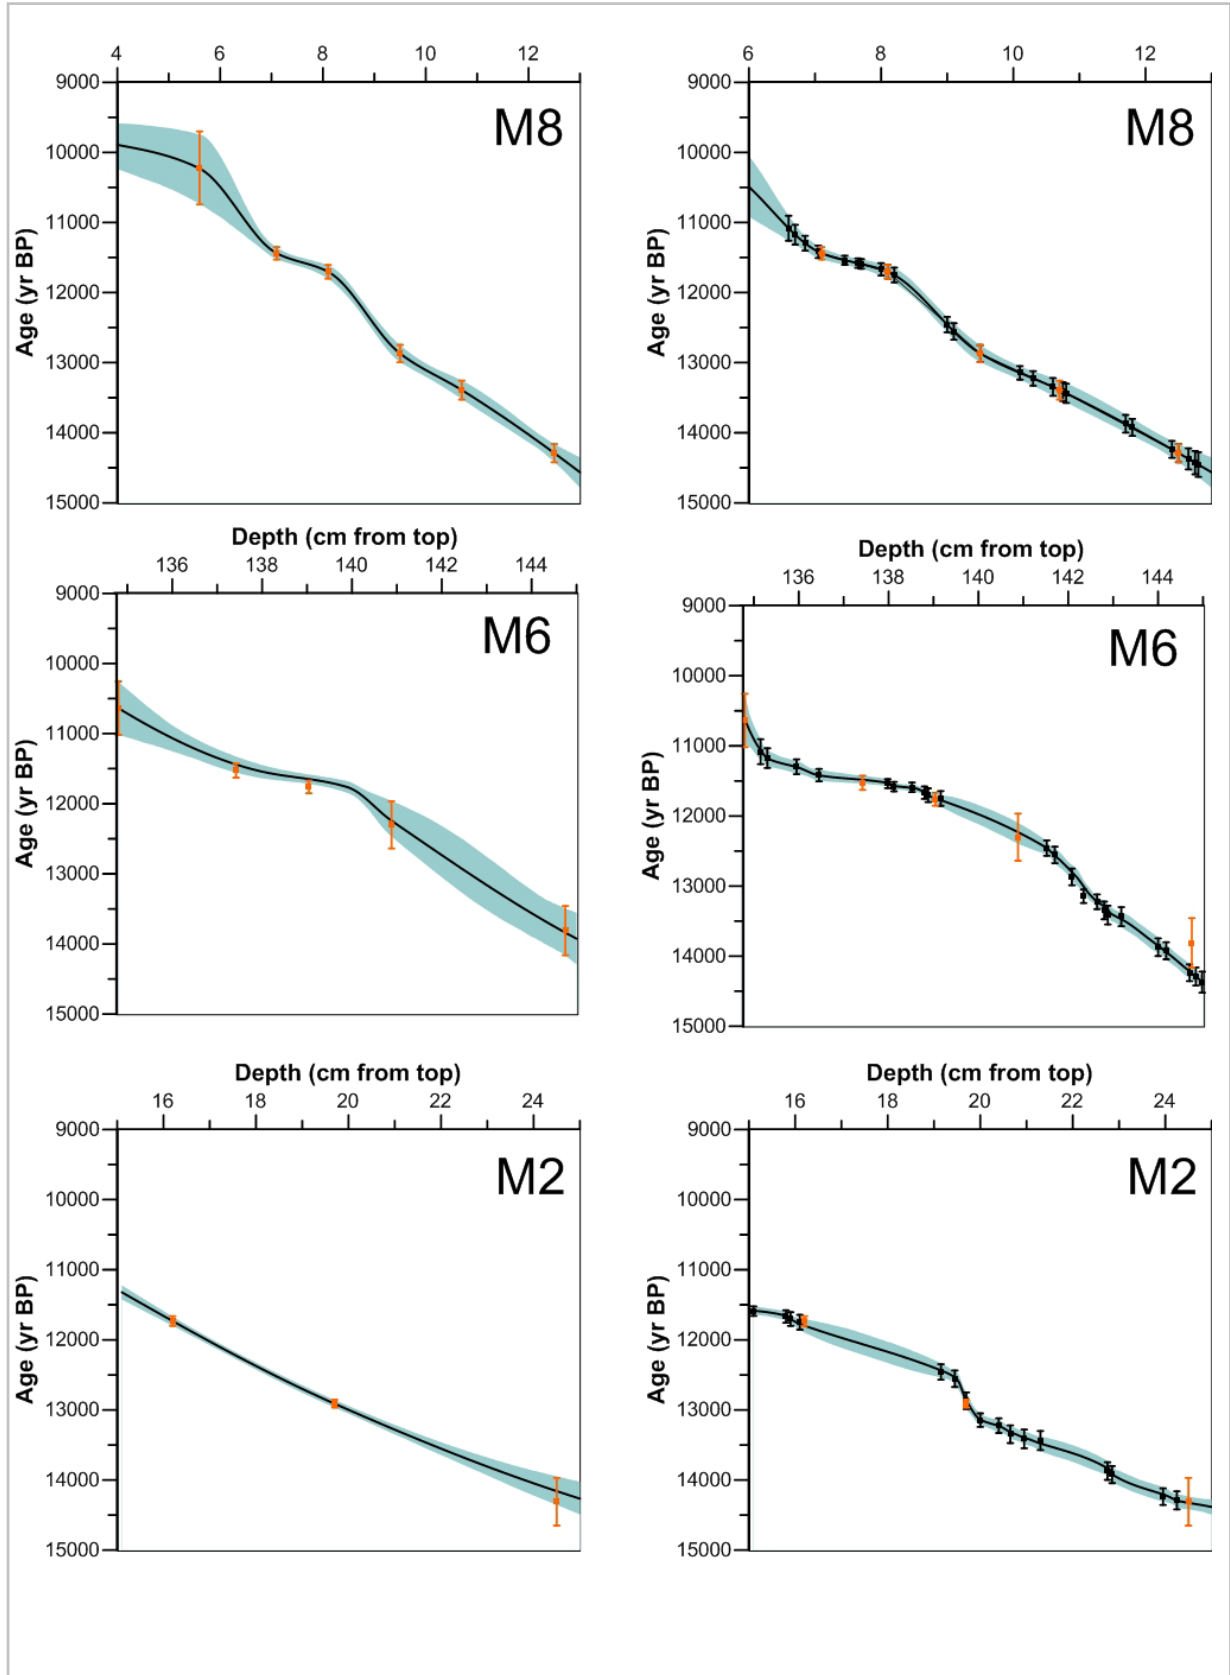

Figure 4.4. Depth-age models of samples M2, M6 and M8 (Milandre Cave). Left side: individual depth-age models. Right side: depth-age models after the tuning. The outer shaded zones define the 95% uncertainties. In orange color are represented the measured ages and in black color the tuned ages. Please note the different depth scale for sample M8.

U decay constants: $\lambda_{238} = 1.55125 \times 10^{-10}$ (Jaffey et al., 1971) and $\lambda_{234} = 2.82206 \times 10^{-6}$ (Cheng et al., 2013). Th decay constant: $\lambda_{230} = 9.1705 \times 10^{-6}$ (Cheng et al., 2013).

* $\delta^{234}\text{U} = ([^{234}\text{U}/^{238}\text{U}]_{\text{activity}} - 1) \times 1000$. ** $\delta^{234}\text{U}_{\text{Initial}}$ was calculated based on ^{230}Th age (T), i.e., $\delta^{234}\text{U}_{\text{Initial}} = \delta^{234}\text{U}_{\text{measured}} \times e^{\lambda_{234} \times T}$.

Corrected ^{230}Th ages assume the initial $^{230}\text{Th}/^{232}\text{Th}$ atomic ratio of $4.4 \pm 2.2 \times 10^{-6}$. Those are the values for a material at secular equilibrium, with the bulk earth $^{232}\text{Th}/^{238}\text{U}$ value of 3.8. The errors are arbitrarily assumed to be 50%.

After tuning, the record of stalagmites from Milandre Cave show continuous growth of the samples as it follows: i) sample M2 (15.1 to 26.6 cm depth) over 11586 ± 63 to 14570 ± 166 y BP interval, ii) sample M6 (135.05 to 145.18 cm depth) over 10963 ± 187 to 14546 ± 140 y BP interval and iii) sample M8 (6.5 to 13.25 cm depth) over 10985 ± 223 to 14705 ± 285 y BP interval (Fig. 4.5 B). Growth rates range from 0.006 to 0.222 mm/y (overall mean 0.047 mm/y) in sample M2, from 0.007 to 0.192 mm/y (overall mean 0.053) mm/y in sample M6, and from 0.004 to 0.073 mm/y (overall mean 0.028 mm/y) in sample M8.

4.4.2. STABLE ISOTOPES ($\delta^{18}\text{O}$ AND $\delta^{13}\text{C}$) RESULTS

As the three stalagmites were precipitated in the same passage of the cave within a distance of 50 m, we assume that all grew under very similar environmental conditions. Calcite $\delta^{18}\text{O}$ values are influenced by (i) $\delta^{18}\text{O}$ of the drip water, (ii) temperature in the cave (mean annual temperature at the surface of the cave), and (iii) kinetic effects during calcite precipitation, leading to simultaneous enrichments of heavier isotopes in the calcite and a positive correlation between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ (Fairchild and Baker, 2012 and citations therein). For $\delta^{18}\text{O}$ we consider kinetic effects as negligible in our samples, as proven by the good replication between the isotopic signal of the three samples and also by parallel track replicates in the same sample (e.g. M6 and M8). The samples are located in a part of the cave not affected by seasonal changes in temperature, and we assume that long term changes in the cave temperature will affect their isotopic composition simultaneously. Finally, differences between $\delta^{18}\text{O}$ values of coeval samples may be given by slight differences in $\delta^{18}\text{O}$ of the drip water. At our site this can be related mostly to the mixing of seasonal precipitation water and its retention time in different epikarst reservoirs, and may differ at the individual dripping sites. A significant influence of these factors was observed mainly in the $\delta^{13}\text{C}$ composition of sample M2, where higher mean values compared to the other samples was observed (Fig. 4.5). Otherwise, changes in $\delta^{13}\text{C}$ of Milandre samples are mainly related to changes in soil microbial activity and vegetation type above the cave (Schmassmann, 2010).

The amplitude of the $\delta^{18}\text{O}$ signal in all three samples is remarkably similar and highlights the proxy quality of their $\delta^{18}\text{O}$ signal. In further discussion we will refer to the sample with the highest sampling temporal resolution, namely M6.

Figure 4.7. $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ time series (black lines) of speleothem M6, source-effect corrected $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_{\text{corr}}$, orange line), and autumn to spring temperature reconstruction (AWS T) based on $\delta^{18}\text{O}_{\text{corr}}$ and 0.69 ‰/°C transfer function (orange line).

$\delta^{18}\text{O}$ calcite values from Milandre Cave are closely related to surface temperatures, with low $\delta^{18}\text{O}$ values corresponding to low surface temperatures and high $\delta^{18}\text{O}$ values to warmer temperatures (Schmassmann, 2010, Hasenfratz et al., in prep).

Figure 4.7 presents the high resolution isotopic record of sample M6. For chronozone nomenclature we used the GICC05 (Lowe et al., 2008) and the modified GICC05 terminology, as published by von Raden et al. (2012) based on the Gerzensee isotopic stack. Table 4.3 summarizes the chrozones, the depth in M6 sample covered by each chronozone, age onset of each chronozone, average temporal resolution and the isotopic composition.

A pattern of short-term variation in $\delta^{18}\text{O}$ is overprinted by the long-term trend between GI-1a and GI-1e (Bølling-Allerød interval, B/A). There, distinct variations with a negative isotopic shift of 0.6 - 0.7 ‰ VPDB were identified, representing transition phases in GI-1d, GI-1c2, respectively GI-1b. During interstadial intervals, such as GI-1a, GI-1c1 and GI-1c3, the amplitude of secondary-variation is only 0.2 -0.3 ‰ around the mean isotopic value of the intervals. In $\delta^{13}\text{C}$, a 3 ‰ VPDB negative trend is observed over GI-1e to GI-1c. A 0.6 ‰ positive shift is observed during the last 200 y of GI-1b (Fig. 4.7). Overall, these isotopic fluctuations during GI-1d to GI-1b did not influence the growth rate of the sample, which shows a relatively constant rate of 0.018-0.023 mm/y. A slower growth rate is observed during GI-1a and GI-1d, with an average of 0.012 mm/y.

Isotopic event	Depth (cm from top)		Age (y BP)			Duration	Average isotopic data

Table 4.3. List of isotopic events (nomenclature based on Gerzensee defined chrozones, van Raden et al., 2012), their location in the M6 sample depth, time interval covered and their mean duration based on the modified M6 chronology. For each chronozone mean temporal resolution of isotopic sampling and mean stable isotopic composition is given. * Full extension of GI-1e is not recorded in sample M6.

A 1.8 ‰ VPDB negative shift in $\delta^{18}\text{O}$ marks the transition into GS1 (Younger Dryas interval, YD). The first half of the YD (between 12 025 - 12 565 y BP) shows a 0.4 ‰ more negative mean isotopic composition (-9.1 ‰) compared to the second half (between 11 650 -12 025 y BP, -8.7 ‰ VPDB). Secondary $\delta^{18}\text{O}$ oscillations of around 0.6 ‰ are observed in the first half of the YD, and a 1.2 ‰ event is superimposed on the gradual positive transition during the second half. The overall positive trend during YD is also reflected by an increase in the growth rate of the sample from 0.028 to 0.037mm/year. In $\delta^{13}\text{C}$ a + 1 ‰ VPDB change is observed just before the YD transition (between 12 717 -13 020 y BP), and a second positive shift of 1.6 ‰ is observed between 12 325 - 12 495 y BP. A minimum in $\delta^{13}\text{C}$ (average -7.7 ‰) is observed between 12 375 to 12 245 y BP. Between 11 600 to 12 130 y BP, the $\delta^{13}\text{C}$ shows second-order oscillations of around 0.6 ‰ varying around a mean of -9.2 ‰. Positive shifts

of 2.2 ‰ in $\delta^{18}\text{O}$ and of -1.2 ‰ in $\delta^{13}\text{C}$ mark the transition into the Early Holocene.

During the early Holocene, the isotope profiles of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ present short isotopic events of high amplitude (around 0.6 ‰ amplitude in $\delta^{18}\text{O}$ and 1‰ in $\delta^{13}\text{C}$) that overprinted the negative trend in both isotopes. A minimum of -7.95 ‰ in $\delta^{18}\text{O}$ was measured during early Holocene (between 11 350 - 11 450 y BP).

For comparison, fresh calcite precipitated between 2012 and 2014 in the sampling location of sample M6 shows isotopic values of around -6.7 ‰ for $\delta^{18}\text{O}$ and -12.1‰ for $\delta^{13}\text{C}$. This suggests temperatures comparable with present during the Early Holocene in the Jura Mountains, with less developed vegetation and soil cover above the cave.

The timing and amplitude of the successive cold and warm events are generally in agreement with other evidence from this region and Central Europe. Changes of 2.1 ‰ in $\delta^{18}\text{O}$ during GI-1a / GS1 and 1.9 ‰ VPDB during GS1/Holocene, as recorded in speleothem M6 calcite, are very similar to changes in the isotopic composition of lake carbonates from the region. Shifts of 2.5 ‰ during GI-1a / GS1 and 2.2 ‰ VPDB during GS1/Holocene, are reported from Ammersee Lake (von Grafenstein et al., 1999), of around 2.2 ‰ VPDB for both transitions from Gerzensee Lake (Lotter et al, 2012, Fig. 4.8). The small differences may be related with the fact that $\delta^{18}\text{O}$ values of the lake carbonates represent annual air temperature changes in the region (von Grafenstein et al., 2012, von Raden et al., 2012), whereas our record is biased towards cold season air temperatures. The positive isotopic trend within the Younger Dryas event is observed in most of the records (e.g., Milandre Cave, Chauvet Cave, Ammersee, NGRIP) confirming the suitability of the isotopic signal of speleothems from Milandre Cave to capture regional and super-regional climatic fluctuations.

Isotope event	GICC05 age, y BP	GICC05 error	GERZENSEE age, y BP	GERZENSEE error	MILANDRE age, y BP	MILANDRE error	GICC05-MIL years	GRZ-MIL years

Table 4.4. Comparison between the onset of major isotopic events as recorded in Greenland ice core chronology (GICC05, Rasmussen et al., 2006, Lowe et al., 2006), Gerzensee Lake (GRZ, van Raden et al., 2012) and Milandre record (our study).

Timing of $\delta^{18}\text{O}$ shifts shows a very good agreement (within errors) with other regional terrestrial $\delta^{18}\text{O}$ records from Chauvet Cave (Genty et al., 2006), Gerzensee Lake (van Raden et al., 2012, Lotter et al., 2012), Ammersee Lake sediments (von Grafenstein et al., 1999), and from the Greenland ice core chronology (GICC05, Rasmussen et al., 2006, Lowe et al., 2000, Fig. 4.8). Before the YD event, the Milandre isotopic profile display consistently older ages for warm and cold interval transitions if compared with GICC05 and Gerzensee stack, and younger for the YD transitions (Table 4.4). Nevertheless, the disagreement falls within the age model errors of the records. An exception is observed

between Milandre and Gerzensee records for the onset into GI-1c2 and GI-1c1 chronozones, which is most probably related to a bias in the age model construction of both records.

Figure 4.8. Comparison between $\delta^{18}\text{O}$ record from Milandre Cave and $\delta^{18}\text{O}$ records from Chauvet Cave (Genty et al., 2006), Gerzensee Lake (van Raden et al., 2012, Lotter et al., 2012), and Ammersee Lake (von Grafenstein et al., 1999), and from the Greenland ice core (GICC05, Rasmussen et al., 2006, Lowe et al., 2006). Dashed lines indicate the boundaries of important chronozones in M6 time series.

4.4.3. TRACE ELEMENT RESULTS

Trace element concentrations were measured in samples M2 and M8. Here we consider the results obtained from sample M8, due to a better age model control. On the same time interval, sample M2 shows excellent agreement with the observed trends and values in M8 sample. Based on our age model, the trace element profiles cover the 11 502 to 13 263 y BP time interval (GI-1b to Early Holocene), with a temporal resolution of 0.6-2.2 years. In this study we consider Mg and Sr as well-established indicators of effective rainfall and groundwater residence time in the karst aquifer above the cave (Fairchild and Baker, 2012). Higher concentrations of Mg and Sr are interpreted to reflect longer groundwater residence times at times of lower precipitation and effective recharge, respectively (Baldini et al., 2002; Hellstrom and McCulloch, 2000; McDonald et al., 2004). The positive correlation between the two elements could indicate prior calcite precipitation in the bedrock during these low effective moisture time intervals (Fairchild and McMillan, 2007). Al is common in the “impulse laminae” (Fairchild and Baker, 2012 and references therein), representing enrichment of drip water in colloid-transported material in response to high infiltration events, or fracture fed flow. Concentration of Si in calcite was suggested to be related to the rate of wind-blown silicate supply and weathering rates above the caves (Hu et al., 2005).

Both Mg and Sr show a general decreasing trend in their concentration over the Younger Dryas (Fig. 4.9). Concentration from the onset to the end of the YD decreases from around 688 mg/kg to 377 mg/kg for Mg and from 87 mg/kg to 54 mg/kg for Sr. Around 12 450 y BP we observe a drop of 23 mg/kg in the concentration of Sr and in the concentration of Mg, most probably related to climate-induced hydrologic changes (increase in precipitation) at the surface, at a time of reduced vegetation cover at the cave surface (indicated by more positive $\delta^{13}\text{C}$).

Al concentration in the sample varies between 1 - 227 mg/kg around a mean 14.5 mg/kg. After 12 350 y BP a frequent occurrence of impulse laminae rich in Al is observed. Si concentration varies between 230 - 12 780 mg/kg, with a pronounced increase in concentration between 12 740 – 12 900 y BP (peak around 12 800 y BP).

Figure 4.9. Time series of trace element concentration (Si, Al, Sr and Mg) and stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) during the Younger Dryas interval

4.4.4. TEMPERATURE RECONSTRUCTIONS BASED ON SPELEOTHEM PROXIES

4.4.4.1. PREVIOUS RESULTS

Samples for water inclusion analysis were obtained from sample M2 (noble gas based reconstructions, NG) and M8 (water $\delta^{18}\text{O}$ and δD) in order to reconstruct absolute temperatures in the cave/at the cave surface at the time of calcite formation. Protocols and results are presented and discussed in detail in Vogel et al. (in prep.) and Affolter et al. (in prep.). The ages of the fluid inclusion samples (mean age of their sampling interval) are based on the M2 and M8 chronologies presented in sub-chapter 3. Table 4.5 presents a summary of the results (water concentration in calcite and absolute temperature reconstructions). To account for a $+1.2^\circ\text{C}$ temperature offset observed between modern calcite temperature reconstructions and modern cave temperature, Affolter et al. (in prep.) applied an identical correction to the reconstructed temperatures. Based on several replicates, the authors propose a mean temperature of $6.2 \pm 0.9^\circ\text{C}$ during Allerød, $4.2 \pm 0.9^\circ\text{C}$ for YD and $7.3 \pm 0.9^\circ\text{C}$ for Early Holocene. For NG-based reconstruction (Vogel et al., in prep.) temperatures of around $3.7 \pm 2.3^\circ\text{C}$ were calculated for Allerød, $1.2 \pm 2.0^\circ\text{C}$ for YD, and $6.3 \pm 2.6^\circ\text{C}$ for Early Holocene. Reconstructions for the Allerød and early Holocene agree well within errors with the ones obtained by Affolter et al. (in prep.), while YD reconstructions shown a stronger cooling (Fig. 4.10), at times with cave temperatures just above the freezing point.

Sample	Age	Water content	Temperature	
	years BP		$^\circ\text{C}$	2σ
M2-162	11607	8.9	6.3	2.6
M2-179	12339	7.2	0	3
M2-192	12762	11.1	1.2	2
M2-199	12969	14.4	3.7	2.3
M2-214	13391	20	2.2	1.5

Sample	Age	Water content	Temperature	
	years BP		$^\circ\text{C}$	2σ
M8-6	10974	0.37	6.6	0.9

Table 4.5. Overview of absolute temperature reconstruction results based on fluid inclusion analysis in sample M2 (NGT, Vogel et al., in prep.) and M8 (Affolter et al., in prep.). Ages represents mean ages of the sampled interval based on the tuned age models of each sample.

Finding an explanation for the temperature offset between the two methods is difficult but may be related to one, or a combination, of the following factors: i) analytical errors, and a series of replicated samples is recommended for sample M2 (using both methods), ii) methodological errors (Meckler et al, submitted), iii) a climate-induced difference between mean annual temperature at the surface (reflected in the cave temperature and NG concentration of fluid inclusions) and the autumn to spring season temperature (as reflected by the isotopic composition of fluid inclusions), or iv) in the cave and/or in the sample specific conditions that could alter the geochemical signal and concentrations. The results obtained from the isotopic composition of the fluid inclusions in Milandre speleothems are considered more robust due to i) replicated analysis, and ii) reliable analogy with modern conditions (Affolter et al., submitted in revised form).

4.4.4.2. $\delta^{18}\text{O}$ / TEMPERATURE TRANSFER FUNCTION

Climatic changes at the surface are transmitted to the cave through chemical and physical properties of the drip water. If the calcite is deposited in or close to isotopic equilibrium, $\delta^{18}\text{O}$ of speleothems is dominated by the $\delta^{18}\text{O}$ ratio of surface precipitation (Fairchild and Baker, 2012 and citations therein). Several studies show that, if excluding eventual changes in the moisture source area and moisture path, temperature exhibits the strongest influence over changes in $\delta^{18}\text{O}$ of precipitation at the cave site, typical for sites in the mid-latitudes (Dansgaard, 1964; Rozanski et al., 1997; Kern et al., 2014). For the period between 1994-2001, $\delta^{18}\text{O}$ in Swiss precipitation is significantly related to air temperature, having a gradient 0.56 ‰/ °C at 500 m alt., and no relation between $\delta^{18}\text{O}$ and the amount of precipitation was found (Schürch et al., 2003). Effective infiltration and residence time in the epikarst control the $\delta^{18}\text{O}$ of drip water and in the speleothems calcite, respectively.

Above Milandre Cave, as a result of evapotranspiration, the effective infiltration during the warm season (April to September) is limited. This is confirmed not only by calculations (Hasenfratz, 2012), but also by monitoring (underground river discharge, vadose flow and drip rate counts in several cave locations, Perrin and Kopp, 2005; Hasenfratz, 2012; Affolter et al, submitted in revised form). All confirm that the karstic aquifer is recharged mainly between October to April and is drained in summer. An open question for Milandre site is if the drip water $\delta^{18}\text{O}$ signal i) is biased towards the season with highest effective infiltration (in this case October-March, as suggested by Hasenfratz et al. in prep.), or ii) this cold season signal is buffered towards a mean annual $\delta^{18}\text{O}$ signal as a result of a long residence time of the water in epikarst of up to several years, as suggested by Affolter et al.(in review).

In order to isolate in the speleothem $\delta^{18}\text{O}$ signal the influence of the local surface temperature, we have corrected the $\delta^{18}\text{O}$ in M6 and M8 samples for isotopic changes that occurred in the source area of the moisture, i.e. the North Atlantic Ocean. Between 14 700 and 10 500 y BP the relative sea level (RSL) rose from - 77 to - 35 m (Bard et al., 2010). Therefore, considering a change of -0.008 ± 0.002 ‰ VPDB per meter of sea level rise (Duplessy et al., 2007), we corrected the Milandre isotope data for the so-called “ice volume effect”, as presented in Figure 4.7 (orange line). This correction is based on the assumption that there was no major shift of the Atlantic vapor source compared to present. We will refer to the correct isotopic data as $\delta^{18}\text{O}_{\text{corr}}$.

To calculate a $\delta^{18}\text{O}$ /temperature transfer function for the YD transitions, and to quantify atmospheric temperature reconstructions over long time intervals (Late glacial to present) we used several lines of evidence obtained from research on Milandre Cave speleothems. The aim was also to test the long-term reliability (across the Holocene) of the 0.69 ‰/°C transfer function developed for the past 300 years by

Hasenfratz et al. (in prep.), by adopting an independent approach. We compiled recent results from three analytical techniques, applied independently to our three samples, that deliver temperature variations in the cave and at the cave surface: i) $\delta^{18}\text{O}$ and δD measurements of fluid inclusions in stalagmite M8 ($\delta^{18}\text{O}$ was calculated based on δD and $\delta^{18}\text{O}_{\text{calc}}$ values in Fig. 4.10, Affolter et al., in prep.), ii) based on noble gas concentrations in the gas inclusions of M2 sample (Vogel et al., in prep), and iii) using a $\delta^{18}\text{O}$ /temperature transfer function calculated for the last 300 years in stalagmite M6 (Hasenfratz et al., in prep, see also Appendix).

Figure 4.10. Transfer function calculation based on calcite powder isotopic composition in sample M8 and absolute temperature reconstructions based on fluid inclusion analysis (M8 sample, red dots with errors, Affolter et al., in prep.) and noble gas temperatures (M2 sample, yellow dots with errors, Vogel et al., in prep.). Black numbers represent mean isotopic composition of calcite for the time intervals represented by the dotted black lines. Gray lines and numbers represent average values for the absolute temperature reconstructions, as used in the calculation for transfer functions. Please refer to the text for details.

For the YD we compared the calcite powder $\delta^{18}\text{O}_{\text{corr}}$ values of stalagmite M8 and the absolute temperature reconstruction based on the fluid inclusion method listed above. Mean calcite powder $\delta^{18}\text{O}_{\text{corr}}$ values are presented in Fig. 4.10. A $\delta^{18}\text{O}_{\text{corr}}$ depletion of 1.6 ‰ was measured during the Allerød/Younger Dryas transition (GI-1a/GS1), and an enrichment of 2.4 ‰ during Younger Dryas/Holocene transition (GS1/Holocene). To compare the isotopic shift with absolute temperature changes based on fluid inclusion analysis was not a straightforward calculation. The data obtained from water inclusion analysis do not fully agree over the YD interval. This situation presented two possibilities to determine a mean temperature shift over the intervals of interest: i) to consider only the Affolter et al., (in prep.) results, which have the advantage of the most replicates and a calibration with modern calcite in the cave (Fig. 4.10, left side, gray line and values), or ii) choose a mean temperature value between both methods (which fall within error limits, Fig. 4.10, right side, gray line and values). Using the first approach, temperature shifts of 2°C, respectively 3.1°C, result in simple transfer function of 0.80 ‰/°C for Allerød/Younger Dryas and 0.77 ‰/°C for Younger Dryas/Holocene (Fig. 4.9). Using the

second approach, a temperature shift of 3°C, respectively 4.3°C, result in simple transfer function of 0.53 ‰/°C for Allerød /Younger Dryas and 0.56 ‰/°C for Younger Dryas/Holocene. Nevertheless, the $\delta^{18}\text{O}$ -temperature coefficient calculated for Late Holocene (0.69 ‰/°C, Hasenfratz et al., in prep) falls well within the range of values estimated for this Late Glacial interval (0.53 - 0.80 ‰/°C) using both approaches. This i) offers strong evidence regarding the validity of the 0.69 ‰/°C transfer function over millennial-scale intervals in samples from Milandre Cave, and ii) implies that the temperature dependency of the isotopic composition of regional precipitation has remained relatively constant (or was affected by minor changes) over Late Glacial and present-day period. Supporting evidence for this assumption is presented by Würth et al. (2004), who report a constant $\delta^{18}\text{O}$ -temperature coefficient of 0.9-1.1 ‰/°C during Late Glacial interval and across the Holocene at a higher elevation European cave (Germany, Hölloch Cave, 1440 m alt). The 0.2 ‰/°C difference within the two transfer functions can be attributed to the difference in altitude between the two cave sites and/or different methods used to calibrate the data.

4.4.4.3. COLD SEASON TEMPERATURE RECONSTRUCTION AT MILANDRE SITE

Temperature changes at the surface are calculated using the $\delta^{18}\text{O}_{\text{corr}}$ values (Fig. 4.7) and a 0.69 ‰/°C transfer function. Temporal resolution of the reconstruction varies between 2 to 16 years (Table 4.3). Mean AWS surface temperatures for each chronozone are summarized in Table 4.6. Mean temperatures fluctuate between 5.0-5.5°C during GI-1e and GI-1a, with the highest temperatures just after the penultimate deglaciation. Lowest temperatures (around 5.0°C) are observed during the cold stages GI-1d and GI-1b. Our data suggest small changes in temperature (around 0.5 °C) for the GI-1d and GI-1c intervals, and point towards a gradual cooling of around 1.2° C (from 5.4 to 4.2° C) during the GI-1a/GS-1 (Allerød/Younger Dryas, AL/YD) transition, respectively a rapid 1.4 °C warming (from 4.6 to 6.0° C) during the Younger Dryas-Holocene (YD/HO) transition. During the YD event a gradual positive trend is observed, from mean values of 3.5 to 4.6°C. For comparison, autumn to spring temperatures (October to May, AWS T) measured for the interval 1960-2010 at Fahy meteo station (600 m alt, MeteoSchweitz) average 5.7 °C.

Isotopic event	Age (y BP)	AWS T (°C)		
		Mean	Min	Max
GI-1e*	14546	5.50	5.10	6.15
GI-1d	14234	5.03	4.79	5.18
GI-1c3	14143	5.30	4.68	5.46
GI-1c2	13952	5.11	4.77	5.31
GI-1c1	13857	5.45	5.19	5.66
GI-1b	13453	5.04	4.75	5.28
GI-1a	13147	5.38	5.12	5.59
GS1	12576	4.18	3.47	5.59
Early Holocene	11598	6.02	5.45	6.23

4.4.5. TEMPERATURE EVOLUTION AND ENVIRONMENTAL CHANGES IN JURA MTS. BASED ON MILANDRE CAVE SPELEOTHEM PROXIES

4.4.5.1. COMPARISM OF MILANDRE-DERIVED TEMPERATURE AND REGIONAL RECONSTRUCTIONS

A comprehensive comparison of quantitative temperature reconstructions in the region, using various approaches, is given in Mangy et al. (2006). Most of the studies report temperature changes during the warm season (JJA) and the warmest month of the year (July, Fig. 4.11). Winter temperature reconstruction from Lake Le Locle (47°N/ 7°E, 915 m alt, Magny et al., 2001) suggest stable YD temperatures, both during the coldest month (from -2 to -3 °C) and mean annual temperatures (from 5 to 5.5 °C). The same study indicates high lake levels and slightly drier (lower precipitation) during the YD.

Calcite-based reconstructions from Milandre Cave add new evidences of regional absolute temperature changes during the cold season (autumn to spring, AWS T, Fig. 4.11). Based on this new evidence, a 0.3 to 0.5 °C decrease in temperature takes place during the cold oscillations over Bølling and Allerød (GI-1d to GI-1a). A slightly larger cooling during the warm season of around 0.5-2°C is suggested by both the pollen and chironomid-based reconstructions from Lake Lautrey (Peyron et al., 2005) and Gerzensee pollen and cladoceran records (Lotter et al., 2000). When comparing the reconstruction during larger temperature shift events, during GI-1a /GS1 transition (Allerød/YD) the 1.2°C shift is similar to the temperature shift of 1.5-2°C inferred from chironomide-based reconstructions from the Swiss lakes of Hinterbergsee (Heiri et al., 2003) and Egelsee (Larocque-Toble et al., 2010). However, this temperature decrease is smaller when compared to estimates in the order of 3°C (July temperatures) from Lac Lautrey (Heiri and Millet, 2005) and 5°C summer (JJA) temperature estimates from Gerzensee Lake (von Grafenstein et al., 2000).

Figure 4.11. Comparison between AWS T at Milandre site and regional temperature reconstruction from Lake Gerzensee (von Grafenstein et al., 2000).and Lake Lautrey (Heiri and Millet, 2005)

The record from Milandre Cave shows that the first part of the YD (12 750 -12 030 y BP) was colder than the second part (12 030 – 11 653 y BP). The inferred AWS T averages 3.9 °C in the first part of the YD, and 4.6 °C in the latter. This pattern, including a high-internal variability during the YD, is apparent in a number of European temperature reconstructions in Central and NW Europe (e.g. von Grafenstein et al., 1999, Brooks and Birks, 2000, Peyron et al., 2005).

The centennial 1.3°C warming before the YD/Ho transition (centered at around 11780 y BP) has not been reported before. Replication of the event in two samples from Milandre (original chronologies) can be considered strong evidence for its existence. The short 40-year long mid-YD isotopic event observed in regional lake proxies from Ammersee and Lake Lautrey (von Grafenstein et al., 1999; Magny et al., 2006) is not present in the Milandre records.

The 1.8 °C YD/Ho shift in regional AWS T is lower compared to other regional temperature reconstructions. Regional low-land warm season paleotemperature records show a range of 1.5 - 3°C (Peyron et al., 2005; Magny et al., 2006; Lotter et al., 2000; Larocque-Toble et al., 2010), 3.9° C from the Central Alps (chironomid, Samartin et al., 2012), or even 6°C from tree rings (Tinner and Theurillat, 2003) and coleopteran records in northern France (Ponel et al., 2007). Mean annual temperatures around the Alps during the transition are reported to have increased by an order of 3-6°C (Eicher, 1994; Schwander et al, 2000).

During the early Holocene, temperature reconstruction above Milandre Cave suggests AWS T of around 0.4 °C above present values. The cooling event dated between 11 350 -11 450 y BP agrees well with the Preboreal Oscillation (PBO, e.g. Lotter et al., 1992). This short cooling event is described as a drop of 2°C in July T in the Central Alps (Maloja Riegel, Switzerland, Ilyashuk et al, 2009), 0.5–3.5 °C in the Lake Lautrey pollen and chironomid records (Peyron et al., 2005; Magny, 2006) and of 2°C in the Le Locle pollen record (Magny et al., 2001).

4.4.5.2. LATE GLACIAL ENVIRONMENTAL CHANGES AT MILANDRE SITE

The Milandre data set shows a detailed sequence of climatic and environmental changes in the Jura Mountains. during the last deglaciation. After the last glacial maximum, calcite starts to form in Milandre Cave speleothems around $14\,546 \pm 140$ y BP, indicating temperatures in the cave (= mean annual air temperature at the surface) above 0°C. The cave environment reacted shortly after the onset of warm conditions in the Swiss lowlands ($14\,590 \pm 196$ y BP, Gerzensee record, von Raden et al., 2012) and high alpine regions ($14\,708 \pm 40$ y BP, Siebenhengste record, Luetscher et al., 2015). Previous research provided evidence of changes in the hydrological cycle, with an increase in precipitation and moisture availability at the onset of GI-1d and the Holocene (Cupillard et al., 2014 and references therein). Temperatures at the site at the transition into GI-1d (Bølling) were around 6.6°C, approximately 1.0°C higher compared to modern conditions. A decrease of 0.9 °C in temperature occurred over a time span of 146 y during the first part of the GI-1d. Between GI-1e and GI-1a the highest and lowest temperatures are around 5.7 °C and 4.8°C respectively. The amplitude of cold minor oscillations in temperature is generally similar to the ones of decadal variations recorded in the first part of the YD event, and a third of the amplitude of the big shift that occur at the onset of the YD. The isotopic oscillations GI-1d and GI-1c2 have a duration of around 80 y, while GI-1b extends over 305 y (Table 4.4), longer than the timing calculated from Gerzensee data (258 y, von Raden et al., 2012), and GICC05 (212 y, Rasmussen et al., 2006).

During GI-1e, forests gradually form in the north of the Alps under rather continental conditions (Theuerkauf and Joosten, 2012). These forests were composed mainly of pine and birch, and where the

Figure 4.12. Comparison between AWS T at Milandre site (red line, our study), variations in the water content of calcite in Milandre Cave (Vogel et al., in prep, Affolter et al., in prep), hydrological-driven changes in Mg concentration of sample M8 (our study), vegetation and soil evolution above the cave ($\delta^{13}\text{C}$ of sample M2 and M8), changes in the Lake Lautrey relative level (Peyron et al., 2005), variations in AMOC straight (relative to 16 000 y BP, Ritz et al., 2013) and alkenone-based sea-surface temperatures from western Mediterranean core ODP-977A (Martrat et al., 2007).

dominant forest composition until the early Holocene. Pronounced negative shifts in $\delta^{13}\text{C}$, until around 14 150 y BP (Fig. 4.12), likely represent shifts in the relative abundance of vegetation and soil development based both on increased temperature and moisture availability at our site. The cooling events centered at 14 210 and 13 950 y BP (GI-1d and GI-1c2) do not seem to affect vegetation development in the area, probably due to their short extent and rather small amplitude.

After the onset of GI-1b we observe a 140 y delay of the vegetation response, with a decline between 13 145-13 310 (± 85) y BP. Changes in temperature and water availability (drier periods) induce a degradation of the forest, with low soil productivity. Nevertheless, the vegetation generally has an immediate positive response (within 10 y) at the transition into warmer conditions (e.g. into GI-1a).

Around 12 880 y BP begins a decline in both temperature and vegetation development. An abrupt 1.3°C decrease in temperature between 12 565 - 12 746 (± 100) y BP marks the transition into the YD, followed by a series of low-frequency warmer/colder oscillations, until around 12 030 (± 134) y BP. Based on multiple proxy data sets (isotopic composition, trace elements concentration, water content in calcite) this first part of YD (12 750 -12 030 y BP) was colder and drier compared to the second part (12 030 – 11 653 y BP). The second part exhibit also low-amplitude high-frequency oscillations in temperature overprinted on the general increasing trend. Compared to the 1°C increase in AWS T during the YD, regional summer T reconstructions show a 3°C decrease (from 18.4 to 15.5°C , Magny et al., 2006). Although significant cooling is associated with the YD event, generally we observe an increased effective infiltration in the epikarst (wetter conditions) across this interval. A hydrological partition of YD is observed based on Mg and Sr concentration (Fig. 4.9), with hydrological conditions changing around 12 350 – 12 450 y BP. Increased water availability in the second part of the YD is also suggested by higher frequency of flushing/flooding events in the cave environment (Al concentration peaks, Fig. 4.9) between 12 350 (± 119) y BP and 11 800 (± 90) y BP. This bi-partite structure of the YD was already discussed in previous studies of terrestrial records (Bakke et al., 2009 and references therein). Magny et al., (2001, 2006) and references therein suggest a lowering of lake levels in the Jura Mountains in the first part of the YD (until around 11 934 y BP) due to dry summers and wet winters, followed in the second part by a different seasonal pattern, characterized by dry winters and wet summers. At Milandre, the coldest and driest conditions within YD occurred between 12 350 - 12 030 y BP, in agreement with the progressive lowering of regional lakes (Fig. 4.12) and with the age of the maximum Younger Dryas (Egesen) glacier advance in the Central and Eastern Alps, at 12 200 - 12 300 (± 1500) years BP (Ivy-Ochs et al., 1999; Ivy-Ochs et al., 2006). The vegetation also responded to the changes in temperature and water availability. Following the important temperature transition in the YD, an accentuated vegetation decline is recorded between 12 465 - 12 365 (± 100) y BP. Vegetation recovery starts around 12 210 y BP, and returns to pre-YD conditions only around 11 900 (± 123) y BP (Fig. 4.12, $\delta^{13}\text{C}$). Drier conditions have been inferred for the Younger Dryas in Middle Europe (Walker, 1995; Zolitschka et al., 1992), with a reduction of 25% of precipitation compared to modern conditions in Switzerland (Wohlfarth et al., 1994). In addition, changes in the amount of precipitation within the Younger Dryas are reported from different regions of Europe. In the first part of the YD, drier conditions are observed in Poland and western Germany, whereas in the Netherlands, Switzerland and the Jura Mountains a trend from wetter, towards drier conditions, has been found for the second part (Lücke and Brauer, 2004 and citations therein). Interestingly, our data support an increase in moisture availability (effective infiltration) towards the second part of the YD. No permafrost conditions developed at our cave site during the YD, as proven both by the continuous growth of calcite in the cave, and by the temperature reconstructions.

The GS-1/Holocene transition is characterized by an abrupt 1.4 °C change in temperature over approximately 60 y (11 600 - 11 660 y BP), with an almost immediate response of the vegetation. Temperature reconstructions based on fluid inclusions from Milandre speleothems suggest the onset of climatic warming already around 11 765 y BP, before the beginning of the major increase in calcite $\delta^{18}\text{O}$. A similar observation was made in pollen-based reconstructions from Gerzensee Lake sediment, where the JJA temperature rise preceded the oxygen-isotope signal by several decades (Lotter et al., 2000), although these observations were not supported by cladoceran-inferred July temperatures reconstructions at the same site. A high amplitude centennial-scale event (11 748-11 843 y BP, peak at 11 785 y BP) ended 100 y before the transition to the Holocene (Fig. 4.12). For the speleothem-based reconstruction, the low resolution of water inclusion analysis allows a mixing of calcite precipitated during the last 200 y of the YD (during which the warm spell occurred) and the results are therefore biased. Higher resolution reconstructions and replicates in other samples could bring more answers regarding this issue.

After the transition into the Holocene, a water deficit at the Milandre site is indicated (decreased water content of the calcite) by a negative trend in temperature (Fig. 4.12). A 30 y long cold spell, centered at 11 573 (± 42) y BP occurred 20 y after the transition, while a new minimum in temperature was reached at 11 434 (± 79) y BP, 175 y after the transition to the Holocene. Pollen and cladoceran-inferred summer temperatures suggest changes that occurred over 190 – 260 y (Lotter et al., 2000). At the Milandre site, vegetation was little affected by the negative trend in temperature during this 175 yearlong period, and the maximum development of soil/vegetation for the studied interval (and close to present day conditions) reached around 11 380 (± 67) y BP.

4.4.6. LOCAL INFLUENCES OF THE VARIATION IN NORTH ATLANTIC ATMOSPHERIC CIRCULATION

The sea-ice-atmosphere system of the North Atlantic Ocean plays a major role for the climate of north-western and central Europe, by cooling surface air temperatures and influencing the position of the storm tracks (Wanner et al., 2001). After the onset of the last deglaciation, episodic discharges of fresh-water into the North Atlantic caused a weakening of the Atlantic Meridional Overturning Circulation (AMOC) sufficient to affect the European climate (Grafenstein et al., 1999 and references therein). Our new data show the close relationship between the changes in AMOC state and temperature/ moisture availability at the Milandre site (Fig. 4.12). The onset of YD occurred at a slow state of AMOC, and mid-YD hydrologic changes at the site occurred shortly after its resumption (Fig. 4.12, Ritz et al., 2013). Interestingly, across the YD we did not observe a close association between temperature and moisture availability at the Milandre site and changes in the North Atlantic Sea surface temperature, as observed for example in previous deglaciation intervals in other regions of Switzerland (see Chapter 2).

Regarding the YD event, previous studies suggest a strong similarity between several European climate proxies in terrestrial and marine records, with Late glacial climate shifts almost synchronous over wide regions (van Raden et al., 2014 and references therein). Differences in the regional responses are attributed to the gradual repositioning of the polar air masses and storm tracks from central to north Europe (Bakke et al., 2009; Lane et al., 2013). Southward expansion of Atlantic sea ice (as far as 52°N, Broecker, 2006) at the onset of YD induced abrupt changes in westerly circulation towards a stronger and more zonal jet over central Europe. Milandre Cave was situated at the southern limit of the polar front during the YD (Lane et al., 2013) and recorded its dynamics over this particular cold event. Around 12 680 y BP the vegetation decline starts at the site, and a coeval increase in Si concentration in Milandre calcite indicates an increase in storminess during the autumn to spring seasons (when maximum water

infiltration occurs in the cave), broadly coincident with regional reduction of vegetation cover and wind intensity changes (Bakke et al., 2009; Theuerkauf and Joosten, 2012; Magny et al., 2006). Nevertheless, during the YD warmer and moisture masses prevailed at the latitude of our cave site compared to the north of Europe (latitudes north of the sea-ice limit) where cold and dry masses enabled, for example, the formation of permafrost (Theuerkauf and Joosten, 2012). Throughout the YD, the climate system in the North Atlantic region was generally unstable (e.g. Bakke et al. 2009; Brauer et al. 2008, our study). At the Milandre site we observe a more stable first part of the YD compared with its second part, with an increasing trend in temperature and moisture availability across the YD, similar to conditions described in North Europe in proxy and model reconstructions (Bakke et al., 2009 and references therein). The establishment of wetter conditions at our cave site (46°N) after $12\,100 \pm 100$ y BP follow most probably the gradual northward retreat of the polar front and subsequent increased moisture delivery into Western Europe (around $12\,240 \pm 40$ y BP, Lane et al., 2013) as a result of retreat of sea ice in the North Sea around $12\,150$ y BP (Bakke et al., 2009). The latter study suggest that the last 400 years of YD were characterized by a regime “repeatedly ‘flickered’ towards interstadial conditions”, similar to the high isotopic variability reflected in the isotopic profile of our samples in the second part of the YD before the rapid transition to the Holocene.

The good preservation conditions of climate-induced environmental changes (vegetation, temperature, moisture availability) in the stalagmites from Milandre site are indicative of the very high sensitivity of this cave speleothems, not only at regional scale, but equally on hemispheric temperature and hydrologic changes.

4.5. CONCLUSIONS

A multi-proxy approach was used to reconstruct in high detail cold-season temperature changes and environment evolution over the Late Glacial-Holocene interval at Milandre Cave site (Swiss Jura Mountains). Timing of chronozones show very good agreement with regional terrestrial $\delta^{18}\text{O}$ records (e.g. von Grafenstein et al., 1999, Genty et al., 2006, van Raden et al., 2012, Lotter et al., 2012, Luetscher et al., 2015).

A new high resolution cold-season temperature reconstruction of the region is provided. Coeval samples from Milandre Cave started to grow shortly after the last deglaciation, around $14\,546 \pm 140$ y BP, as mean AWS temperatures around 5.5°C prevailed at the cave site. Over Bølling and Allerød intervals mean AWT fluctuate between 5.0 - 5.5°C . A 1.2°C gradual cooling makes the transition into YD, and a 1.4°C warming marks the transition into Holocene. The first part of YD, between $12\,750$ - $12\,030$ y BP, was colder and drier compared to the second part, between $12\,030$ – $11\,653$ y BP. Vegetation responded almost immediate to major changes in temperature.

Our paleo hydrologic reconstructions are consistent with interpretations based on climate archives from central and northern Europe. The establishment of wetter conditions at our cave site (46°N) after $12\,100 \pm 100$ y BP follow most probably the gradual northward retreat of the polar front and subsequent increased moisture delivery into Western Europe (around $12\,240 \pm 40$ y BP, Lane et al., 2013) as a result of retreat of sea ice in the North Sea around $12\,150$ y BP (Bakke et al., 2009).

Furthermore, as the $\delta^{18}\text{O}$ -temperature coefficient calculated for Late Holocene falls well within the range of values estimated for this Late Glacial interval, brings evidences that the source of the moisture in Swiss Jura Mountains did not overcome major changes over the last $14\,550$ y BP.

5.1. INTRODUCTION

Although the warm climate of the Holocene, which is considered as an interglacial, there is increasing interest in studying the climate variability during this period (e.g. Allen et al., 2007; Wanner et al., 2011 and references therein; Wirth et al., 2013). Detailed and well- dated paleoclimate archives show that significant temperature variation occurred in Europe during most of the Holocene (Litt et al., 2009; Büntger et al., 2011; Esper et al., 2014). Although their amplitudes cannot be compared with the large millennial-scale temperatures of glacial climates (e.g. Dansgaard/Oeschger cycles), the social-economic impact was considerable (Wanner et al., 2011 and references therein; Schennan et al., 2013)

As there is much to be learned about the mechanisms that could be responsible for the observed climate variability during the Holocene, high-resolution and precisely-dated archives are needed. Natural proxies such as tree rings, lake sediments, ice cores, cave deposits, peat, and corals allow us to evaluate climate variability and forcing mechanisms in time. Each of these proxies presents its own weaknesses and strengths in terms of temporal resolution, spatial coverage, age model construction and target season (e.g. Jones and Mann, 2004 and references therein). Furthermore, all proxy records are an indirect measurement of climate change and need some kind of transfer function to translate their signature into climate parameters (e.g. water availability, temperature).

One of the main goals of the SINERGIA project was to construct a complete and highly-resolved Holocene record of the air temperature from Switzerland. Milandre cave was chosen as a sampling site for several reasons. First, during the last decades, Milandre Cave was the subject of multiple scientific studies, addressing its hydrology and physical parameters in the cave aquifer (e.g., Jeannin, 1996; Perrin et al., 2003a, 2003b; Perrin, 2003) which allow a good understanding of this speleaeen environment. Second, Schmassmann (2010) has already shown the suitability of the cave stalagmites from Milandre Cave to host reliable proxies of climate and environmental changes from annual to millennial scales.

The difficulty to determine any transfer function over long time intervals (e.g. Holocene) is given by the fact that several climate parameters influence the proxies, and/or the parameters will not remain constant over time. In order to overcome this issue, we adopted the following strategy: test the reliability of the transfer function independently, based on multiple paleothermometer proxies in speleothems from Milandre Cave. This calculation was done both for Late Holocene and Late Glacial intervals.

5.2. SITE AND SAMPLE DESCRIPTION

Milandre Cave is located in the Ajoie region of the Swiss Jura Mountains (47°49'N / 7°02'E, 400 m asl, Fig. 4.1). Surface meteoric parameters in the region are measured at the nearby Fahy weather station (47°42'N / 6°94'E, 596 m asl, 200 m higher than our cave site) which is operated by the Swiss Federal Office of Meteorology and Climatology (MeteoSchweiz). The mean annual average of surface air temperature for the interval 1960-2010 is 8.6°C, with mean winter and summer temperatures of 1.1°C and 16.4°C, respectively. A high seasonality is present in the outside air temperature, with maximum mean temperatures in August with 17.2°C, and minimum in January with 0.4°C. Precipitation is relatively equal over the year; with precipitation averaging 292 mm in summer and 224 mm in winter. Snowfall may occur from November to March, although this region exhibits a mild climate during winter (mean temperature above 0°C, MeteoSchweiz).

Milandre Cave formed in the limestone of the St.-Ursanne Formation (Tabular Jura unit). The cave has a total length of 10.5 km and develops on two levels. The upper level is fossil and covered by only

30-80 m of host rock. The lower level is 30 m lower below the upper level and used by the 4.6 km long underground Milandriner River. Our sampling campaign focused on a fossil gallery of the cave, named Galerie des Fistuleuses (see Fig. 4.2). This part of the cave can be accessed by a 15 m long tunnel, which was enlarged by mining in 1967. Cave air temperature is 9.8°C and constant throughout the year (± 0.2 °C; monitored between 2012 and 2014). Air flow circulation in this part of the gallery was under detection limit (< 100 l/s air flow), and relative humidity is 100 %. Values of $p\text{CO}_2$ between 0.3 to 1.41 % were measured (2008 - 2014, measuring campaigns) although $p\text{CO}_2$ in the gallery can rise up to values around 4 %, especially during late autumn and early winter (pers.comm. Ph. Häuselmann).

Sample M6 is a 145.2 cm long candlestick stalagmite and was active (precipitated calcite on its top) when collected in autumn 2011. The sampling location, from a slightly elevated lateral side of the Galerie des Fistuleuses, 200 m south of the northern entrance of the cave, assured a minimal influence of in-cave processes, such as high ventilation and flooding events. The sample was fed by a soda straw dripping at 0'15'' to 6'00'' time intervals. The sample has no visible hiatus, is composed by columnar fabric crystals, and well defined macroscopic laminae are observed on the top 20 cm of the sample (Fig. 5.1). Axial holes (aligned along the axis of the sample) are a common feature in M6. They are possibly related with the action of the falling drop, which reduces the deposition rate of the calcite at the apex of sample (Shtober-Zisu et al., 2014). Laminations were observed between the pores, a clear indication that the calcite deposition continued at a normal rate. The focus of the present study is the top 135.9 cm of the M6 sample, for data obtained in the lower part of the sample please refer to Chapter 3 of this thesis.

5.3. METHODS AND RESULTS

^{230}Th -ages were determined on a multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS, Thermo-Finnigan Neptune) at the Department of Geology and Geophysics, University of Minnesota. Details of the methods, including standards used for mass fractionation and yield correction can be found in Edwards et al. (1987) and Cheng et al. (2013). For analysis, between 170 and 200 mg of powder was drilled along discrete growth horizons (Fig. 5.1). The ^{230}Th -dating results for the top 135.9 cm of stalagmite M6 are provided in Table 5.1. The low U content, averaging 70 ppb (min. 37.7 and max. 225.5 ppb) and presence of detrital Th resulted in high chronological uncertainties. Ages are in chronostratigraphic order, except a reversal (sample M6_32) at 56.75 cm depth in the sample. This reversal could not be resolved by the statistical program used to construct our age model (COPRA algorithm, Breitenbach et al., 2012) and therefore was excluded. Therefore, the final age model of sample M6 is constrained by using 36 ^{230}Th ages, all in stratigraphic order within their 2σ dating uncertainties. The resulting median of the 1000 Monte Carlo simulations and its 95% confidence interval (blue colour) are presented in Fig. 5.2. Growth rate of the sample varies between 0.018 and 0.698 mm/year, around a mean of 0.195 mm/year.

For stable carbon and oxygen isotope analysis, a total of 3170 samples were micromilled continuously at 0.1 mm (top 4.4 cm) and 0.5 mm increments from 0 to 4.4 cm and from 4.4 to 135.9 cm, respectively. Powdered samples were measured using a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. Results are reported relative to the international Vienna Pee Dee Belemnite (VPDB) standard. Analytical errors for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ are 0.07 and 0.06 ‰ VPDB (1σ), respectively (Fleitmann et al., 2009). The temporal resolution of the oxygen and carbon isotope profiles varies between subannual and 92 years, with an average of 4 years. $\delta^{18}\text{O}$ values vary between -5.15 and -8.36 ‰ around a mean of -6.82 ‰ VPDB. Superimposed on the long-term trends distinct short-term

U decay constants: $\lambda_{238} = 1.55125 \times 10^{-10}$ (Jaffey et al., 1971) and $\lambda_{234} = 2.82206 \times 10^{-6}$ (Cheng et al., 2013).Th decay constant: $\lambda_{230} = 9.1705 \times 10^{-6}$ (Cheng et al., 2013).

Figure 5.1. Polished section of stalagmite M6 (Milandre Cave) showing micromilling paths for isotopic analysis, sampling locations for ^{230}Th calcite dating (black dots) and dating results.

variations of 1 to 1.5 ‰ are observed. $\delta^{13}\text{C}$ values vary between -8.63 and -11.68 ‰, around a mean of -10.31 ‰ VPDB. To compare, mean isotopic values of calcite precipitated between June 2012 and July 2014 are -6.68 ‰ VPDB for $\delta^{18}\text{O}$ and -12.10 ‰ VPDB for $\delta^{13}\text{C}$.

Figure 5.2. Depth-age models of sample M6. Error bars represent 2σ errors and the blue shaded zones define the 95% uncertainties of the age model.

5.4. PALEOCLIMATIC SIGNIFICANCE OF STALAGMITE $\delta^{18}\text{O}$ VALUES

$\delta^{18}\text{O}$ of precipitation at Milandre site is dominated by three main drivers, i) the source of precipitation (North Atlantic Ocean for our region), ii) changes in the moisture trajectory, and iii) the temperature at the site (Schürch et al., 2003). The North Atlantic Ocean is considered to be the main source of moisture at our study site, with contributions of around $17.3 \pm 5.7\%$ from Mediterranean moisture sources could occur mainly during the summer months (Sodemann and Zauber, 2011). During the Holocene, only minor changes occurred in $\delta^{18}\text{O}$ of the ocean. For example, as a result of ice caps melt between 7 000 and 11 000 y BP, the 24 m rise in the relative sea level could induced changes of - 0.10 to - 0.28 ‰ in the isotopic signal (Dupplesey et al., 2007, Grant et al., 2012). No major trajectory reorganization of westerlies air masses was reported in literature. The $\delta^{18}\text{O}$ of modern precipitation in Switzerland, and therefore at our cave site, is strongly governed by the air temperature (Schürch et al., 2003; Kern et al., 2014). At present, the $\delta^{18}\text{O}$ -temperature relation is $0.56\text{‰}/^{\circ}\text{C}$ at 500 m asl. (Schürch et al. 2003), comparable with values calculated for other regions of central Europe ($0.60\text{‰}/^{\circ}\text{C}$; Rozanski et al., 1992; 1997).

If deposited close to equilibrium conditions, the calcite $\delta^{18}\text{O}$ of stalagmites from Milandre should capture a direct temperature signal transmitted through the $\delta^{18}\text{O}$ of the drip water. If we consider a constant annual temperature in the cave, shifts in the M6 $\delta^{18}\text{O}$ record (Fig. 5.3) should be related with changes in the $\delta^{18}\text{O}$ of local precipitation and its seasonality. Thus, the timing and amount of recharge to the karst aquifer above Milandre Cave is an important control on drip water $\delta^{18}\text{O}$ values. Results of the stable isotope monitoring of the drip water and the precipitation at Milandre site indicates that the dripping water feeding the stalagmite is very close with the weighted average of the precipitation $\delta^{18}\text{O}$ over the interval June 2012 to July 2014. Comparing $\delta^{18}\text{O}$ of drip water from different locations in the cave, a well mixing of waters in soil, epikarst and the vadose zone above the cave before being

transferred to the cave drip sites is suggested (Affolter et al., submitted in revised form). Monitoring of drip rates at M6 sampling site (between June 2012 to July 2014, Affolter et al., submitted in revised form) also supported earlier observations that the Milandre karst aquifer is generally recharged during the cold season and drained in the summer (Jeannin and Grasso, 1995a, 1995b; Jeannin, 1996; Perrin et al., 2003; Perrin and Kopp, 2005). Water excess is positive from November to April, as summer evapotranspiration controls the water balance that recharges the karst aquifer between the months of May and October. Seasonal variability was observed both in the $\delta^{18}\text{O}$ values of precipitation (ranging from 3.4 ‰ to -21.8 ‰ SMOW) and $\delta^{18}\text{O}$ of drip water, with two observations: the $\delta^{18}\text{O}$ signal of drip water is delayed by 8 to 10 months and its amplitude is smoothed (Affolter et al., submitted in revised form).

Several methods were used to test whether the M6 calcite was deposited close to isotopic equilibrium. Hasenfratz (2012) successfully used the “Hendy test” (Hendy, 1971) for calcite precipitated during the last 2000 y. For longer time intervals, Häuselmann et al. (in prep., Chapter 4 of this thesis) has shown the striking similarity between the M6 isotopic signal and other coeval stalagmites from Milandre Cave, proving the reliability of M6 in preserving the climate signal.

Figure 5.3. Stable isotopes profile of stalagmite M6. Thick lines represent the 11 points running average data-set

In summary, we argue that changes in the calcite $\delta^{18}\text{O}$ are closely related to changes in drip water $\delta^{18}\text{O}$, which in turn is strongly influenced by temperature-controlled variations in the $\delta^{18}\text{O}$ of precipitation. As infiltration takes place mainly in the cold season, stalagmite M6 it is very well suited to capture variations in autumn to spring (AWS) temperature at the cave site. A strong argument to support this hypothesis was brought by Hasenfratz (2012) and Hasenfratz et al. (in prep.). Hasenfratz et al. (in prep.) developed a temperature transfer function by correlating the M6 calcite $\delta^{18}\text{O}$ to regional historical and

instrumental temperature reconstructions for the last 300 y (Luterbacher et al., 2004; Xoplaki et al. 2005). A variation of 0.69 ‰ corresponds to an increase of 1°C during the cold season (October to May) surface air temperature. Häuselmann et al. (in prep., Chapter 4 of this thesis) tested the long-term validity of this transfer function, and observed the calcite $\delta^{18}\text{O}$ shows the same bias towards cold season temperature also during the Late Glacial-Early Holocene interval.

5.5. TEMPERATURE VARIABILITY AND VEGETATION EVOLUTION OVER THE LAST 11 000 YEARS BP

We have shown that there are strong indications that the relation between precipitation $\delta^{18}\text{O}$ and temperature has remained relatively constant (or was affected by minor changes) over Late Glacial and Late Holocene (Häsenfratz et al., in prep., Häuselmann et al., in prep.). Thus, we applied the calculated transfer function (0.69 ‰/°C) to the Holocene M6 $\delta^{18}\text{O}$ data and extended the autumn to spring temperature reconstruction (AWS T) until 11 000 y BP. For the AWS T reconstruction for the interval between 11 000 to 14 550 y BP please refer to Chapter 4 of this thesis (Fig.4, upper side).

Figure 5.4 presents the AWS T variability over the last 11 000 ka BP as recorded in the calcite $\delta^{18}\text{O}$ of M6 stalagmite. The variations are reported to the average temperature of the interval, which is 5.87 °C. The 5.87 °C value is also similar with the mean autumn to spring temperatures measured between 1960 and 2010 at Fahy meteorological station, which is 5.8 °C.

Overall, AWS T varies between 4.8 to 6.9 °C, around a mean of 5.9°C. High frequency and high amplitude variability is observed in the dataset. We filtered the dataset by applying an 11 points running average. Several peaks in temperature (warm and cold) were observed. Temperature below 5.5°C are centred around 478 ± 83 , $1\,175 \pm 119$, $4\,619 \pm 206$, $7\,965 \pm 399$ y BP, while temperatures above 6.2°C peak around 325 ± 93 , 718 ± 103 , 790 ± 125 , $1\,390 \pm 174$, $1\,490 \pm 152$, $1\,798 \pm 75$, $1\,856 \pm 72$, $5\,826 \pm 142$, $8\,924 \pm 124$ and $9\,600 \pm 554$ y BP. Around 19 colder and 11 warm centennial and multi-centennial intervals were observed. Figure 5.4 presents their distribution and temporal extension, with positive (negative) intervals as red (blue) boxes. Please note that currently no statistical program was used to delimitate the temporal boundaries for these intervals.

Variations in the vegetation density, as recorded in the $\delta^{13}\text{C}$ profile, suggest that changes in temperature alone do not seem to affect the development of vegetation at the site. A lower frequency and amplitude variation is observed compare with temperature evolution. An increase in vegetation density and soil formation are observed between 4 700 – 5 717 y BP and 498 - 975 y BP. The highest vegetation density is recorded between 2 080 – 4 700 y BP, followed by a decrease between 975 – 2 080 y BP, and from 498 y BP until today.

Fig. 5.4. (next page) Autumn to spring temperature reconstruction (AWS T, October to May) based on from calcite $\delta^{18}\text{O}$ from Milandre cave (Swiss Jura Mountains). Temperature variability is reported to the mean value of the Holocene interval. Red and blue boxes represent warmer and colder centennial intervals in the reconstruction. Yellow boxes represent intervals of minima in total solar irradiance (Renssen et al., 2006) and blue arrow maxima in ice-rafted debris (IRD) in North Atlantic Ocean (Bond et al., 2001)

5.6. DISCUSSIONS AND OUTLOOK

Recently it has been shown that the calcite $\delta^{18}\text{O}$ in samples from Milandre Cave represent reliable qualitative proxy for $\delta^{18}\text{O}$ in precipitation and linked temperature, as well as $\delta^{18}\text{O}$ in the moisture source (Häuselmann et al., in prep., Affolter et al., submitted in revised form). The new M6 $\delta^{18}\text{O}$ record represents one of the few continuous highly-resolved and precisely-dated Holocene records from Europe, and provides both quantitative and qualitative climate reconstructions of regional and hemispheric relevance. Nevertheless, represents one of the very few high-resolution cold-season temperature reconstructions in Central Europe. The features of reconstructed climate variability at our cave site are in excellent agreement with previous paleoclimate reconstructions over the North Atlantic region, from a regional to a hemispheric scale (later discussed). Nevertheless, its high resolution and accuracy will make possible robust regional intercomparison and bring support in decoupling and understanding the impact of external and internal climate forcings in Central Europe and North Atlantic region.

Our record underlines the teleconnections between the climate in Switzerland and the sea-ice-atmosphere system of the North Atlantic Ocean. We confirm the synchronicity between intervals of colder temperatures (and more negative calcite $\delta^{18}\text{O}$) occurring around intervals of maxima in ice-rafted debris (IRD) in North Atlantic Ocean (Bond et al., 2001; blue arrows in Fig. 5.4). A similar synchronicity was suggested for northern Europe by Niggemann et al. (2003), who investigated speleothem $\delta^{18}\text{O}$ from B7 Cave (Germany). Bond events (Bond et al., 2001) are usually correlated with minima in total solar irradiance (TSI, yellow boxes in Fig. 4, Renssen et al., 2006). Most of the TSI minima intervals have a corresponding cold intervals recorded in Milandre $\delta^{18}\text{O}$ record (and consequently in the AWS T, Fig. 5.4). The role of orbital forcing in driving changes in this mid-latitude region was already observed in other natural archives (e.g. Ivy-Ochs et al., 2012; Wanner et al., 2007; Mangini et al., 2007; Nicolussi and Schlüchter, 2012; Solomina et al., 2015 and references therein). Nevertheless, there are cold events that do not follow any of the patterns earlier discussed, and therefore our record has the potential to deepen our understanding of the regional climate variability (magnitude, duration and frequency of temperature changes) and the nature of its forcing mechanisms.

Despite recent efforts of several research groups in reconstructing climate variability based on speleothem proxies from Central Europe the results do not seem to validate each other (Fohlmeister et al., 2012 and 2014, our study Fig. 5.5). This is probably related with climatic parameter influencing the oxygen isotopic composition of the samples at different cave sites. In detail, $\delta^{18}\text{O}$ variations in stalagmites from Spannagel Cave (Austrian Alps) are suggested to reflect variations in the moisture source region (North Atlantic Ocean vs. the Mediterranean Sea) and/or variations in the seasonality of precipitation (Mangini et al., 2005; Fohlmeister et al., 2013), with a reverse $\delta^{18}\text{O}$ /temperature relation if compared to Milandre Cave. The calcite $\delta^{18}\text{O}$ of speleothems from Bunker Cave (Germany) is expected to be primarily driven by seasonal infiltration of rainfall in the epikarst, similar to Milandre site (Fohlmeister et al., 2012). Nevertheless, these special different relations between temperature, seasonality of precipitation and atmospheric processes (changes in the main source of moisture) could provide important insights in the regional teleconnections (e.g., Casty et al., 2005).

Teleconnection could be observed also with other Northern Hemisphere regions influenced by the North Atlantic climate variability (e.g. North America and Asia). Similar with our dataset, four events punctuating the high Asian monsoon intensity centred at 11 200, 10 900, 9 200, 8 300 and 8 100 y BP are recorded in the stalagmite stable isotope series from China (Dykoski et al., 2005), suggesting that M6 $\delta^{18}\text{O}$ record provides a good base in testing special and temporal teleconnections at a large hemispheric scale.

Figure 5.5. Comparison between $\delta^{18}\text{O}$ record from Milandre Cave and $\delta^{18}\text{O}$ records from Spannagel Cave (COM-NISPA II, Fohlmeister et al., 2013) and Bunker Cave (Fohlmeister et al., 2012)

Not only $\delta^{18}\text{O}$, but also in depth investigation of $\delta^{13}\text{C}$ variation can provide further hydrological and environmental information. For example, several studies (e.g. Wanner et al, 2011; Fohlmeister et al., 2013 and references therein) report changes in the climatic proxies around 6 000 y BP related with enhanced rainout during the Holocene and orbital-induced changes in temperatures seasonality (Fig. 5.6). This trend is not evident in our $\delta^{18}\text{O}$ profile, but it exists in the $\delta^{13}\text{C}$ profile. After 5 717 y BP, a general negative trend is observed in $\delta^{13}\text{C}$ and marks the increase in vegetation density and microbial activity as a result of increase water availability and milder winters.

Figure 5.6. Comparison between AWS T at Milandre site and regional temperature reconstruction of January and July months (Meerfeld Maar, Germany; Litt et al., 2009) and phases of glacier advance and retreats in Swiss Alps (Grindelwald Glacier, Luetscher et al., 2011)

The new Milandre dataset provides a robust base for large areas of research. In the near future, spectral analysis are to be performed on the M6 $\delta^{18}\text{O}$ time series and AWS T record (e.g. Frisia et al, 2003, Niggemann et al., 2003). Furthermore, absolute temperature reconstructions based on the $\delta^{18}\text{O}$ and δH in the fluid inclusions of M6 calcite are now performed at the Institute of Physics (Bern University) using the Affolter et al., (2013) method. These new fluid inclusion data could add further evidences for the reliability of the transfer function used for the last 11 000 years, and in the same time provide novel information regarding any changes in the moisture source of the moisture.

The new gained knowledge of long-term climate variability in our region, as presented in our data set, will be a valuable asset for future climate scenarios models and assessing an important contribution to better evaluate the consequences of different scenarios of climate change.

CHAPTER 6.

CONCLUSIONS AND OUTLOOK

The most important goal of the STALCLIM project was to use and develop the potential of speleothems as paleoclimate and paleoenvironmental archives by coordinating and combining a series of state-of-the-art methods in speleothems proxies. Two different cave settings and time scales were studied, and relative to each cave, we have used speleothems to reconstruct low- to high- frequency climate and environment variability.

Schafsloch Cave, from where sample MF3 was collected, is located in a high alpine setting sensitive to variations in climate and atmospheric circulation. A considerable effort was put into dating, analysing the chemical composition of calcite, and observing the petrography and layer boundaries. Between 130.1 ± 0.4 and 225.8 ± 2.3 ka BP the cave aquifer was influenced not only by changes in temperature and precipitation, but also by the dynamic of a small glacier present above the cave. This detailed study has provided valuable new information on i) the quantitative temperature variations and water availability over glacial-interglacial intervals, and ii) the evolution of a small glacier body intermittently present above the Schafsloch Cave, despite the relatively few precisely dated samples covering the time interval of interest. Changing isotopic composition of the sample suggests possible changes in air mass pathways that may trigger changes in climate. The importance of orbital parameters (summer insolation budget, sustained by increase seasonality) in the major climate shifts during the studied interval is highlighted. Our results place the timing of the penultimate deglaciation at around 131.8 ± 0.6 ka BP, in good agreement with precisely-dated records from North America and Europe, and 2.8 ± 0.7 ka earlier than recorded in Asian monsoon regions. We therefore support the notion that the Asian monsoon system and ITCZ responded largely to wintertime cold anomalies in the North Atlantic and Eurasia.

At the global scale, the scientific community continues to debate the role of internal (changes in the AMOC, rise in the CO_2 concentration) and external factors (insolation, obliquity) in triggering major climate events. This study shows that high-resolution independently-dated records, such as speleothems, represent a key asset in trying to decouple the regional and global impact of these factors over long-term intervals.

Open questions remain regarding the evidence for a “mystery warm interval” during the full glacial stage of MIS 6, which suggests a complete meltdown of the glacier, together with at least two other partial retreat phases. More high resolution data covering MIS 6 in Europe is required in order to improve our understanding on this particular topic.

Interpretation of trace element concentration in speleothem calcite remains a challenge, and even more so if one wants to understand their pattern in a highly-dynamic glacial setting and in subglacial water, for which few modern analogues exist. In the future, details analyses of ratios of Mg and Sr isotopes and the type of organic matter incorporated in the sample (as changes in its content were observed at times when the glacier was present above the cave) can enhance our understanding of the landscape evolution in response to climate change in these high alpine environments. Nevertheless, comparing and building a data sets of chemical (isotopic, trace elements) and biological (organic matter, microbial mats) properties of calcite formed under warm-based glaciers, may advance our understanding in quantifying chemical composition of meltwater and biologic evolution at the base of the glacier.

In the second half of the thesis a multi-proxy, multi-method approach was used to reconstruct in detailed climate and vegetation variability in the Swiss Jura Mountains, together with a new high resolution cold-season temperature change and environment evolution at the Milandre cave site for the last 14 550 y BP. Timing of the chronozones during Holocene-Late Glacial intervals shows very good agreement with regional terrestrial $\delta^{18}\text{O}$ records. Vegetation responded almost immediately to major

changes in temperature. Over Bølling and Allerød intervals mean AWT fluctuate between 5.0-5.5°C. A 1.2° C gradual cooling marks the transition into the YD, and a 1.4 °C warming marks the transition into the Holocene. The first part of the YD, between 12 750 -12 030 y BP, was colder and drier compared to the second part, between 12 030 - 11 653 y BP. During the Holocene, AWS temperature varies between 4.8 to 6.9 °C, with a mean of 5.9°C. An increase in vegetation density and soil formation are observed between 4 700 - 5 717 y BP and 498 - 975 y BP.

The Milandre record highlights the teleconnections between the climate in Switzerland and the sea-ice-atmosphere system of the North Atlantic Ocean. The isotopic data have been combined with external datasets, particularly concerning the long-term evolution of meteoric precipitation patterns, temperature and $\delta^{18}\text{O}$ composition at the sites. The establishment of wetter conditions at this cave site (46°N) after $12\,100 \pm 100$ y BP, is most likely the result of the gradual northward retreat of the polar front and subsequent increased moisture delivery into Western Europe. We also present evidence that the source of the moisture in the Swiss Jura Mountains did not experience major changes over the last 14 550 y BP.

One of the main objectives of this thesis was to develop long and continuous records of climate change in Switzerland. We are confident that the new isotopic and temperature reconstructions based on speleothem-proxies from the Milandre Cave site (Swiss Jura Mountains) will be an important asset in addressing current research topics in the North Atlantic region, such as North Atlantic Oscillation variability, temperature seasonality, and the nature and structure of cold and warm periods in Central Europe.

In addition to the two sites that comprise the main focus of this thesis, lower resolution isotopic and dating analyses were also performed on several other samples from the Jura Mountains and the Swiss Alps (please refer to Table 1.1). More detailed investigation of these samples is recommended with regard to climate variability in Switzerland during the Holocene, the last glacial interval and MIS 5.

ACKNOWLEDGEMENTS

Four years ago, when I started my scientific and personal journey in the STALCLIM project, seems like another lifetime. Presenting this thesis would have been impossible without the support and effort of several people and organizations, to whom I will like to present my deepest gratitude.

THANK YOU, MULȚUMESC, UN GRAND MERCI, DANKE, MERCI VIÛ MAU, EFHARISTO ...

PROF. DR. DOMINIK FLEITMANN, my main supervisor

... for giving me the possibility to perform science in your group
... for your patience and support during all the ups and downs of the project
... for coping with the distance and my stubbornness during the last two years

PROF. DR. MARKUS LEUENBERGER, my co-supervisor

... for accepting to co-supervise my work and for his support during the last year
... for your continuous interest in the speleothem sciences

PROF. DR. CHRISTOPH SPÖTL

... for kindly agreeing to be the external referee of this thesis and for adapting to the limited time provided for that

PROF. DR. FLAVIO ANSELMETTI

... for accepting to chair my PhD defence

PROF. DR. HAI CHENG AND PROF. DR. LARRY EDWARDS

... for performing the ^{230}Th analysis, your collaboration and fruitful discussions

DR. SALLY LOWICK AND DR. PHILIPP HÄUSELMANN

... for proofing the English language of this thesis

DOMINIK, SERAINA, IGOR AND GABY

... for training and assistance in the laboratory methods and procedures

GINA AND ADAM

... for your interest in speleothem sciences and your help in the lab and field campaigns

STEPHANE AND DANIEL

... for your friendship and support
... for building together memories and experiences, both in science and general aspects of life

SEBASTIAN, NADIA AND YVES

... sharing your knowledge, help in the field, and for really helpful comments and suggestions

THOMAS, DORIAN, SALLY, MARIUS, KELLY ANN, MARINA AND ANDREI

... for all the chocolate and coffee time together and for coping with my high energy and bothering

PROF. DR. KARL RAMSEYER, PROF. DR. KLAUS MEZGER, AND SIGRID ZIMMERMANN
... for all the administrative and advising support

CAVE PROTECTION AND SCIENTIFIC COMMISSIONS OF THE SWISS SPELEOLOGICAL SOCIETY
... for allowing us to collect speleothems in Swiss caves and for their support

... for organizing our continuous formation classes, field trips, and young researchers meetings

THE COMMUNITY OF CAVE AND SPELEOTHEM SCIENCES
... for being a great motivation and kindly replying to any requests and questions over the last years

SWISS NATIONAL FUNDS
... for funding the Sinergia STALCLIM project

AND LAST BUT NOT LEAST

A HUGE LIST OF FRIENDS, from the caving community and not only (you all know who you are)
... for giving me a reality check and understanding my absence and low energy sometimes

URS AND MARGARETHA
... for their love, support and patience in coping with two researchers in the family

MAMA, TATA, MAMI, LIANA, GELU, PAUL, AMALIA
... for your great support, love, patience and help, from the moment I arrived in this colorful world until now
... for spending so much time in Switzerland and keeping me free of loads of family responsibilities
... vă iubesc și nu exista cuvinte să vă mulțumesc îndeajuns

PHILIPP
... for continuously being an example in scientific ethics and perseverance
... for understanding my absence, late return home and moody mornings
... for being there anytime for everything

THOMAS EMIL GOTTLIEB
... for your great joy and hugs every time I return home, and not only
... for providing enough distraction from this thesis and constantly reminding me what is really important in life

DEDICATED TO

M.Sc. SILVIA SCHMASSMANN

YOUNG SPELEOTHEM RESEARCHER AND CAVE EXPLORER

(18.01.1982 – 30.12.2013)

***... FOR HER INITIAL STUDY OF SEDIMENTS AND SPELEOTHEMS FROM MILANDRE CAVE AND, IN
THE SAME TIME, FOR HER HARD WORK IN THE EXPLORATION AND PROTECTION OF THE UNDERGROUND
ENVIRONMENT***

APPENDIX

A. DATA

For all practical purposes, for all the samples presented in table supplementary data can be found on the CD enclosed and consists of the following files:

1. Stable isotopes analysis performed at the Institute of Geological Sciences, Bern University
2. ^{230}Th ages measured at the department of Geography and Geophysics, University of Minnesota, USA
3. ^{230}Th ages measured at the Institute of Geological Sciences, Bern University, Switzerland

B. MANUSCRIPTS

Except the manuscripts presented as chapters in this thesis, our research group prepares for publication two papers, which are found in the following pages:

S. Affolter, A. D. Häuselmann, D. Fleitmann, Ph. Häuselmann and M. Leuenberger (submitted in revised form) Triple isotope (δD , $\delta^{17}\text{O}$, $\delta^{18}\text{O}$) study on precipitation, drip water and speleothem fluid inclusions for a western central European cave (NW Switzerland)

A. Hasenfratz, D. Fleitmann, A.D. Häuselmann, F. Lehner, H. Cheng, R. L. Edwards, M. Leuenberger, C. C. Raible, S.F.M. Breitenbach, J. Luterbacher (in prep.) Central European temperature variations over the past two millennia based on a stalagmite oxygen isotope record from the Swiss Jura Mountains

Abstract

Water isotopes are powerful tracers of the hydrological cycle and they have been extensively used for paleoclimate reconstruction. The traditional δD and $\delta^{18}\text{O}$ are namely known to provide information on past precipitation, temperature and atmospheric circulation variations. More recently, the use of $^{17}\text{O}_{\text{excess}}$ parameter derived from precise measurement of $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ gives new insight in tracing the hydrological cycle. Debated and not yet fully understood, $^{17}\text{O}_{\text{excess}}$ could provide, as d-excess, additional information on the atmospheric conditions at the moisture source in parallel to transport processes as well as site effects. In this paper, we investigate the climate signal transmission in water stable isotopes (δD , $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$) from precipitation to cave drip water and finally to speleothem fluid inclusions for Milandre cave in northwestern Switzerland. A two year-long daily resolved precipitation isotope record above the cave has been established and was compared to collected cave drip water (3 months average resolution) and modern as well as early Holocene speleothem fluid inclusions (multidecadal resolution). Amount weighted mean δD , $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$ are -71.0‰ , -9.9‰ , -5.2‰ for isotope compositions of precipitation, -60.3‰ , -8.7‰ , -4.6‰ for cave drip water and -61.3‰ , -8.3‰ , -4.7‰ for the fluid inclusions, respectively. Secondary order proxies have also been derived in precipitation and drip water and present similar values with 18 per meg for $^{17}\text{O}_{\text{excess}}$ whereas d-excess is 1.5‰ more negative in drip water. For fluid inclusions, their interpretation relies on the instrumental precision. Results show that the atmospheric signal is shifted towards enriched values in the drip water and fluid inclusions (δ of $\sim +10\text{‰}$ for δD). A weak seasonality is still visible in the drip water isotope signal but shifted by around 8 – 10 months (groundwater residence time) when compared to the precipitation. Moreover, we carried out the first $\delta^{17}\text{O}$ measurement in speleothem fluid inclusions, as well as the first comparison of the $\delta^{17}\text{O}$ behaviour from the meteoric water to the fluid inclusions entrapment in speleothems. This study on precipitation, drip water and fluid inclusions will be used as a speleothem proxy calibration for Milandre cave in order to reconstruct paleotemperatures and moisture source variations for western central Europe.

1. Introduction

Water isotopes (hereafter discussed as $\delta^{18}\text{O}_\text{p}$) in precipitation rely on the moist air masses history through moisture source, atmospheric circulation and evaporation/condensation processes. On a regional scale $\delta^{18}\text{O}_\text{p}$ varies in function of surface air temperature, amount of precipitation, moisture source origin and rainout effect (Rozanski et al., 1992; Araguas-Araguas et al., 2000). Speleothems are now widely used for continental paleoclimate reconstructions. Understanding the key processes that govern cave climate and hydrology one has to know the boundary conditions, i.e. atmospheric meteorological conditions, evapotranspiration by plants at the surface and processes in the soil and in the transition zone. Only with these prerequisites speleothem data can be interpreted in terms of climate and hydrology (Riechelmann et al., 2011). Cave monitoring studies constitute a new standard for the interpretation of speleothem proxies and characterising the relationship between water isotopes of precipitation and cave drip water is becoming routine in caves worldwide (Cruz et al., 2005; Moerman et al., 2010; Cuthbert et al., 2014; Genty et al., 2014).

Stalagmites in particular allow the reconstruction of climate for long time intervals throughout the Quaternary (Cheng et al., 2009; Fleitmann et al., 2009; Meckler et al., 2012). They can be precisely dated using laminae counting (Fleitmann et al., 2004; Shen et al., 2013; Duan et al., 2015) or more commonly by Uranium-Thorium series analyses (Cheng et al., 2013) and they can provide information on past climate change at high resolution (Henderson, 2006).

Most of the paleoclimate reconstructions are based now on calcite geochemistry (Shakun et al., 2007). Routinely measured are $\delta^{18}\text{O}_c$ and $\delta^{13}\text{C}$ for calcite, which are respectively proxies for moisture supply (Burns et al., 2001; Fleitmann et al., 2003; Kennett et al., 2012; Vaks et al., 2013; Luetscher et al., 2015) and vegetation dynamics (Genty et al., 2010; Rudzka et al., 2011; Blyth et al., 2013) above the cave. Although widely used, $\delta^{18}\text{O}_c$ is influenced by different processes above and in the cave environment such as temperature and humidity driven isotope fractionation of the atmospheric water cycle, fractionation associated with the biospheric exchanges, equilibrium and kinetic fractionation between calcite and soil/karst waters during the passage from the surface into the cave. These effects make the interpretation of $\delta^{18}\text{O}_c$ difficult (Lachniet, 2009).

Fluid inclusions represent past drip water and are consequently relics of past precipitation above the cave at the time when fluid inclusions were closed (Schwarcz et al., 1976). Hence, they can be used as a direct proxy for paleotemperature or moisture history (Fleitmann et al., 2003; van Breukelen et al., 2008; Griffiths et al., 2010). Based on the correlation between mean annual temperature and mean annual $\delta^{18}\text{O}_p$ on a global scale (Dansgaard, 1964) past temperature can thus be reconstructed using for instance the relationship that exists for calcite precipitation at equilibrium (Kim and O'Neil, 1997). However, one has to consider that the seasonal distribution of precipitation is a key factor that could easily yield misleading temperature estimates for the past. Moreover, most cave carbonates are not deposited in oxygen equilibrium with their parent drip waters (McDermott et al., 2006). Thus, it was observed that temperatures calculated on modern speleothems using an empirical relationship (Craig, 1965) were closer to corresponding cave air temperatures. More recently, a new empirical calibration based on several caves data already takes a mean disequilibrium into account (Tremaine et al., 2011) and seems to provide reliable temperature estimates. A multi-proxy method comparison paper (Meckler et al., in review) shows the potential of speleothems for paleotemperature reconstructions by comparing the results of four different paleothermometers that are (i) speleothem fluid inclusions (Dublyansky and Spotl, 2009; Affolter et al., 2014), (ii) liquid-vapour homogenization of fluid inclusions (Kruger et al., 2011), (iii) noble gases concentration in stalagmite water (Vogel et al., 2013), and (iv) clumped isotopes (Meckler et al., 2014). With this objective in mind it is thus important to monitor the isotope proxies from the precipitation falling above the cave to evaluate if the isotopic composition of cave drip and speleothem fluid inclusion water is comparable. So far, most investigations study the relationship between precipitations and drip water, while in this study we additionally investigate the climate signal transmission to speleothem fluid inclusions. Recent developments in speleothem fluid inclusion measurement techniques allow the measurement of both δD_f and $\delta^{18}\text{O}_f$ on a single sample (Arienzo et al., 2013; Affolter et al., 2014). We provide here an extension of the method by measuring $\delta^{17}\text{O}_f$ in fluid inclusion water offering new horizons for paleoclimate research based on speleothems. $\delta^{17}\text{O}$ measurements on water samples were so far achieved using CoF_3 fluorination of water (Landais et al., 2012a), but a more recent laser absorption spectroscopy based technique allows now fast and simple triple isotope measurements on water samples (Steig et al., 2014).

Secondary order proxies d-excess and $^{17}\text{O}_{\text{excess}}$ can be calculated from the triple isotope measurements on water aliquots. Deuterium excess is obtained from hydrogen (δD) and oxygen ($\delta^{18}\text{O}$) isotopes values and is defined as $d = \delta\text{D} - 8 \times \delta^{18}\text{O}$ (Dansgaard, 1964). It carries information about the ocean surface conditions, namely it is used to characterise the disequilibrium conditions at the moisture source. It is mainly dependent on sea surface temperature, normalised relative humidity and wind speed at the moisture source (Jouzel and Merlivat, 1984; Uemura et al., 2008) but is also dependent on local factors such as recycling of local moisture. Similarly to d-excess, $^{17}\text{O}_{\text{excess}}$ is calculated (see section 3.3) from small variations in oxygen isotopes ($\delta^{17}\text{O}$ and $\delta^{18}\text{O}$) and it corresponds to the deviation from the line of 0.528 corresponding to meteoric waters (Luz and Barkan, 2010). It constitutes a promising, but debated parameter to provide additional information on the water cycle (Winkler et al., 2012; Schoenemann et al., 2014; Li et al., 2015). The $^{17}\text{O}_{\text{excess}}$ corresponds to an indicator of evaporation condition at the moisture source (Angert et al., 2004; Barkan and Luz, 2007) and it has been so far mostly studied in the Polar Regions (Landais et al., 2008; Landais et al., 2012b; Schoenemann et al., 2014) and poorly in the lower latitudes (Landais et al., 2010; Luz and Barkan, 2010). Over the ocean, $^{17}\text{O}_{\text{excess}}$ is negatively correlated with the normalised relative humidity (Uemura et al., 2010). A direct link with the relative humidity was observed in coastal area of Antarctica (Winkler et al., 2012) but Schoenemann et al., (2014) showed that in Antarctica, $^{17}\text{O}_{\text{excess}}$ has a strong dependence on the atmospheric temperature during transport due to the temperature dependence of supersaturation that overwhelm any information about the relative humidity. $^{17}\text{O}_{\text{excess}}$ can also be influenced by processes of the terrestrial biosphere (Landais et al., 2007). Local conditions may also influence $^{17}\text{O}_{\text{excess}}$ (Winkler et al., 2012; Steen-Larsen et al., 2014; Li et al., 2015).

In Switzerland, isotopes in precipitations have been surveyed for decades within the isotope network ISOT by the Climate and Environmental Physics at the University of Bern (CEP) financially supported by the Swiss Federal Office for the Environment (FOEN). (Schurch et al., 2003) summarises part of this work for a west-east transect across Switzerland for three distinct areas representing the Jura Mountains (La Brévine station), the Swiss Plateau (Bern station) and the Southern Alps (Locarno station). The study performed at the Mormont station (Fig. 1) constitutes a prolongation of this transect up to the Tabular Jura that constitutes a flat Plateau to the NW of the last elevation of the Jura Mountains and provides additional information on $\delta^{18}\text{O}$ and δD behaviour preventing the rainout effect that may occur when moisture encounters the first

escarpment of the Jura Mountains. The link between $\delta^{18}\text{O}$ in precipitation and cave waters has already been studied in Milandre cave (Perrin et al., 2003a).

In this paper, we present an overview of the hydrogen (δD) and oxygen ($\delta^{18}\text{O}$ and for the first time $\delta^{17}\text{O}$ in drip water and speleothem fluid inclusions) isotope signal transfer in water for a karst system in the Jura Mountains. We investigate the isotopic evolution from precipitation to cave drip water and its final enclosure into the speleothem fluid inclusions, and discuss the preservation of the climate signal. Based on these investigations, we conclude that stalagmites from Milandre cave are well suited for future paleoclimate reconstructions.

2. Site settings

Milandre cave (47.4855° N / 7.0161° E, elevation 373 m a.s.l.) is located in Boncourt (45 km westward of Basel, NW Switzerland) (Fig. 1). Geologically, the cave is part of a karst aquifer belonging to the Jura Mountains geological structure, more precisely it is located in the Tabular Jura unit that is made of subhorizontal Mesozoic limestones overlying Oxfordian marls. Milandre aquifer consists of a few metres thick soil and epikarst that overlie the unsaturated zone of the karst and eventually the phreatic zone (Perrin et al., 2003b).

The cave section shown on Fig. 2 represents approximately one third of the total network. Cave galleries develop mostly along fractures oriented north/south on a horizontal distance of 2.7 km with a total of 10.5 km of galleries and an overall positive elevation of 135 metres. The 4.633 km long Milandrine River flows in the lower part of the caves system which drains a surface catchment area of around 13 km² that is at a mean elevation of 500 m a.s.l. (Perrin, 2003; Perrin et al., 2007). The Milandrine flows directly into the Allaine River after passing a major siphon located at the natural resurgence. Except for this first natural entrance, the cave has a second natural access 30 metres above the siphon. A tunnel to access the former show cave has been built close to the natural entrance to facilitate access for visitors, but in the seventies the exploitation was stopped due to major flooding. The former show cave (200 metres long) is connected at its end to a well preserved fossil gallery called *Galerie des Fistuleuses* (literally “soda straws gallery”) via a second man-made access tunnel (15 metres long) excavated by the Jura caving club and opened in March 1968. A metallic door was placed in this connecting tunnel to preserve the cave site. This entrance remains closed, except for safety reasons when CO₂ concentration levels are too high to allow scientific trips. Land use above the cave is nowadays mainly constituted of forests, pastures and isolated individual constructions, especially above the downstream parts including the monitoring site. An extended description of the hydrological settings (Perrin et al., 2003a), of epikarst storage characteristics (Perrin et al., 2003b) and hydraulics aspects of Milandre cave system (Jeannin, 1996) allow a good understanding of the system.

Our monitoring study focuses on the *Galerie des Fistuleuses* where most of the stalagmites were collected. Furthermore, it has the main advantage of being easily accessible and that the cave climate is not disturbed when the doors remain closed. A detailed topographic map and an extended description are available in (Gigon and Wenger, 1986).

Milandre cave is influenced by the climate conditions prevailing over the study site which are representative for central/western Europe. Annual repartition of moisture fluxes for the northern Swiss Alps has been estimated by (Sodemann and Zubler, 2010) and gives the following results: ~39.5% from North Atlantic sectors, ~23% from Mediterranean area, ~21% from Europe continental source and ~16.5% from Northern Europe. Moreover, the source of precipitation suggests a principal continental contribution for the summer months whereas during winter continental contribution is low and the North Atlantic represents the major input. Contribution of moisture fluxes coming from the Mediterranean occurs mostly in winter, spring and autumn. For our study site we can expect similar conditions.

Mean annual precipitation recorded at Fahy station (Fig. 1) over the period 1960-2011 averages 1055 mm. An increase of 40 mm between the periods 1960-1990 and 1990-2011 is observed. Moreover, seasonal variability is well visible with significantly lower average precipitation amounts (monthly average of 74 mm) in winter (December-January-February, DJF), highest precipitation amount (101 mm) in summer (June-July-August, JJA) and intermediate values (89 mm) in March-April-May (MAM) and September-October-November (SON). Mean annual temperature at Fahy station (2 m above surface) over the last five decades shows maximum mean temperatures in August with 17.2°C and minimum in January with 0.4°C for an overall average air temperature of 8.6°C. It is worth noting that averaged temperatures between the period 1960-1990 and 1990-2011 increase from respectively 8.1°C to 9.2°C showing a significant warming of the Jura Plateau region. Temperature in the soil (5 cm depth) is also recorded at the station and gives mean annual values of 10.3°C between 1990 and 2011 that is 1.1°C more than the surface temperature.

Correlation maps with a spatial resolution of 0.5° x 0.5° and centred on 48°N 7°E were realised using the KNMI Climate Explorer (<http://climexp.knmi.nl/>) and the CRU TS 3.22 datasets for temperature and precipitation (Harris et al., 2014) to investigate the relationship of different climate parameters for NW Switzerland based on available temperature and precipitation (Fahy station, time series 1990-2011) and $\delta^{18}\text{O}_\text{p}$ (Basel CEP station, time series 1986-2010). According to the approach of

(Rozanski et al., 1992), seasonality of time series was removed beforehand. For Fahy station, spatial correlation maps with the CRU TS gridded data indicates that the mean annual temperature and precipitation are representative for central/western Europe, including Switzerland, France (eastern, centre and north), Germany and Belgium. Indeed, local temperature in Fahy station and European temperature are significantly correlated ($r > 0.80$) for most of central Europe. A similar observation made with the amount of precipitation leads to significant correlation ($r > 0.60$) for central/western Europe (Fig. 3b). Correlation maps realised between $\delta^{18}\text{O}$ p in Basel CEP station and temperature show significant correlation ($r = 0.60$, Fig. 3c) with central/western Europe, e.g. Germany, France and Belgium, whereas no correlation is observed with the amount of precipitation (Fig. 3d).

3. Methodology

3.1. Monitoring

A cave monitoring campaign was carried out in the *Galerie des Fistuleuses* between November 2011 and June 2014. Continuous and spot measurements of cave temperature, drip rate, relative humidity and air P_{CO_2} measurements were conducted. Cave air temperature was measured every 15 minutes since October 2012 using a UTL-3 Scientific Dataloggers (GEOTEST, Zollikofen and Snow and Avalanche Research SFL, Davos, Switzerland) at an accuracy of 0.1°C . A Stalagmate Plus Mk2b (Driptych, United Kingdom) was used to monitor drip rates using an acoustic technique (drops per hour) at the M6 site since June 2012 (Collister and Matthey, 2008). The device was placed in an open pot connected to a one litre glass vial through an outlet tube to collect the water in glass bottles which were replaced around every three months (Fig. 2).

In the *Galerie des Fistuleuses*, spot measurements show air flow lower than 100 l/s (Testo 405-V1 device), humidity rate of 100% (Aspirationspsychrometer Hänni device) and P_{CO_2} ranging from 0.30 to 1.41% (continuous (CORA device) and spot (Dräger X-am 5600 device) measurements from 2008 to 2014). Occasionally, the P_{CO_2} concentration in the gallery can rise up to values of around 4%, especially during late autumn and early spring, as a result of processes that still need to be investigated.

Water samples were collected for geochemical analysis at different drip sites where stalagmites were taken (Table 1) to better understand isotope behaviour occurring between precipitation, drip water and its enclosure in speleothem fluid inclusions. The survey includes four drip sites for water isotopes (M4, M6, M9 and Fi-2) and three cave locations for temperature (including M2, M4, M6, M8, M9 and Fi-2). M6, M8, M9 and Fi-2 are located in the same cave chamber (refer to Fig. 2 for site positions).

Temperature and drip loggers were installed in the chamber where M6, M8 and M9 stalagmites were collected, approximately 300 metres after the end of the show cave (Fig. 2). A drip logger instrument was placed at the exact location where water was dripping from a soda straw on M6 stalagmite (from a height of ~ 2 metres). Stalagmite M8 grew close to M6 but was not active when removed. Finally, waters from the three drip sites (M6, Fi-2 and M9 which are 0.5 and 5 metres away from M6, respectively) were collected and analysed to estimate the homogeneity of the drip water chemistry.

3.2. Water isotope monitoring program

Data are based on two meteorological stations from the MeteoSwiss network. Precipitation samples and daily amount data were obtained from Mormont station ($n^\circ 534$, 47.44°N / 7.04°E , altitude 540 m a.s.l.). The precipitation collection campaign was carried between March 2012 and July 2014, and a total of 274 precipitation events were recorded at 8 a.m. local time in an open gauge and stored in 100, 200 or 500 ml sealed glass bottles depending on the precipitation size. One must keep in mind that when collecting in an open gauge, evaporation occurring throughout the day could lead to a fractionation of the precipitation water, especially during the summer. The automated Fahy station ($n^\circ 500$, 47.42°N / 6.94°E , altitude 596 m a.s.l), located 7 km away from Mormont station, has provided daily data of precipitation amounts, mean relative humidity, mean soil and air temperatures since 1960. Both stations are located close to Milandre Cave (Fig. 1) and are therefore used as reference sites.

Cave water samples were obtained from five drip sites corresponding to the sample locations M2, M4, M6, M9 and Fi-2 between November 2010 and June 2014, and are further named “downstream” drip waters. Moreover, additional waters from one secondary intermediate flow tributary of Milandrine River (EN) and three additional percolation samples (ST, VI and GO) with approximately five or six orders of magnitude higher flow than M6 were collected in the upstream part of the cave (Perrin et al., 2003a) and are further called “upstream” cave waters.

3.2.1 Isotope measurements

Water isotope analyses of precipitation and cave waters were performed at the CEP (University of Bern) using a Picarro L2140-i wavelength-scanned cavity ring-down spectroscopy (WS-CRDS) instrument (Picarro Inc., Sunnyvale, CA, USA). For precipitation and drip water analysis, aliquots of water are filled in 2 ml glass vials and sealed with rubber/aluminium

caps. The vials are then placed in a PAL COMBI-xt autosampler (CTC Analytics AG, Zwingen, Switzerland) connected to the Picarro L1102-i for δD and $\delta^{18}O$ and L2140-i for additional $\delta^{17}O$ values. Water is then injected using a syringe five or six times directly into the vaporisation unit of the analyser and the three first values are discarded due to memory effect. Reproducibility of measurements is typically 0.1‰ for $\delta^{18}O$ and $\delta^{17}O$ and 0.5‰ to 1‰ for δD .

For fluid inclusions, we used a new online method based on a Picarro L1102-i WS-CRDS instrument (Affolter et al., 2014) that allows measuring both δD and $\delta^{18}O$ isotopes on a single speleothem sample with precisions better than 0.4‰ for $\delta^{18}O$ and 1.5‰ for δD . Furthermore, accuracy and precision of the new method were also successfully assessed through an inter-laboratory comparison with the CF-IRMS method (Meckler et al., in review). The only modification made to the line is the replacement of the stainless steel capillary connecting the peristaltic pump to the dripping device by a glass capillary (0.18 mm inner diameter). Significant improvement was made on the measurement protocol with a reduction of time from 5 to 2 hours (90 minutes to recover the background condition stability and 20 to 40 minutes for the sample measurement itself mainly depending on the amount of released water) for one speleothem sample measurement, allowing up to five sample measurements per day. To perform $\delta^{17}O$ measurements in speleothem fluid inclusions, the line was connected to a Picarro L2140-i that is able to measure $\delta^{17}O$ in addition to $\delta^{18}O$ and δD . The instrument performance was assessed using the same approach as described in (Affolter et al., 2014). The precision of $\delta^{17}O$ measurements for stalagmite water samples is 0.3‰. Table 2 summarises the precision of the different water isotope measurements. In this study, blocks of calcite of around 0.5 grams were crushed releasing ~0.6 ml of water for fluid inclusions analysis of recent samples (M6), whereas blocks of ~1.5 grams were necessary for early Holocene (M8) samples to provide ~0.5 ml. It is worth mentioning that Holocene values are given here only for a first preliminary comparison to present conditions. For isotope analysis of the calcite ($\delta^{18}O_c$), the samples were measured using a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. 150-200 micrograms of sample were analysed and results are reported relative to the international Vienna Pee Dee Belemnite (VPDB) standard. The analytical error for $\delta^{18}O_c$ is 0.07‰ VPDB (1 σ) (Fleitmann et al., 2009).

3.2.2 $^{17}O_{\text{excess}}$ calibration

The $^{17}O_{\text{excess}}$ measurements made at Bern were calibrated using four internal water standards that themselves were analysed at the *Laboratoire des Sciences du Climat et de l'Environnement* in Paris with the method of CoF_3 fluorination of water to produce pure oxygen that is eventually analysed by dual inlet-IRMS (Landais et al., 2012b). Due to really small differences in $^{17}O_{\text{excess}}$, values are given in per meg (10^{-6}). Corresponding $\delta^{17}O$ values were calculated using Eq. 2 based on the relationship of (Luz and Barkan, 2010) (Eq. 1):

$$^{17}O_{\text{excess}} = \ln(\delta^{17}O + 1) - 0.528 \times (\delta^{18}O + 1) \quad \text{Eq. 1}$$

and consequently:

$$\delta^{17}O(\text{‰}) = ((e^{(^{17}O_{\text{excess}}/1000 + 0.528 \times \ln(\delta^{18}O)/1000 + 1)} - 1) \times 1000) \quad \text{Eq. 2}$$

Table 2 summarises the isotopic values of different internal standard waters used in this study. We experienced discrepancies between values obtained for $^{17}O_{\text{excess}}$ based on the CoF_3 method performed at Paris, our own less-precise equilibration method (Elsig, 2008 #1618) and the high-precision laser-based cavity ring-down measurements. A detailed comparison of the three different methods will be presented in a separate publication. The values presented in this study are based on the four laboratory internal water standards that themselves were calibrated to the international scale by measuring V-SMOW, V-SLAP and V-GISP using the Picarro L2140-i instrument.

4. Results and discussion

4.1 M6 drip discharge

Drip rates between 2012 and 2014 at the M6 site are highly variable and range from 11 drops/hour (October 2012, 2013 and 2014) up to 278 drops/hour (February 2013). A seasonal pattern is clearly visible with the highest drip rates during the winter months (DJF) and the lowest during summer and autumn. Nearby Fi-2 drip site was checked at a three months interval and shows that drip rate was five times higher (with a similar seasonality as at M6) which emphasizes the variability in cave environment and the need of local monitoring. Nevertheless, isotope values for both drip locations are similar (Table 3). Drip rate depends on the aquifer recharge, i.e. on the amount of precipitation above the cave. The comparison between drip rate and precipitation is given in Fig. 4 and shows that both are closely related. Lowest drip rates in summer means that the overlying reservoir is draining out, as the aquifer is less recharged in summer mainly due to increased evapotranspiration (Fig. 1).

However, fairly high precipitation in autumn and winter recharges the aquifer and drip rates are increasing steadily, indicating that cold season precipitation (roughly from September to May) contribute to groundwater replenishment above Milandre cave.

We investigated the relationship between heavy rainfall events and cave drip rates in order to evaluate the response time. During summer when the reservoir is at its lowest level a two day-long precipitation event starting on 23.08.2013 (51.1 mm in total) showed only a slight response in drip discharge two days later (from 28 to 30 drops/hour). On 28.07.2013, a precipitation event (26.5 mm) showed no corresponding signal in the drip discharge but rather a continuous decrease of values. In spring, two consecutive days of precipitation (39.1 mm in total) produced a peak in drip rate (from 64 to 112 drops/hour) around five days later. Another two-day long event starting on 26.04.2013 (total 34.2 mm) gave a response six days later with an increase from 60 to 97 drops/hour. During winter months, an intense precipitation period between 24.12.2013 and 28.12.2013 (85.2 mm in total) led to an increase from 41 to 103 drops/hour around six days later. Overall, drip rates respond within 2-6 days to major precipitation events and drip rate is much more reactive in intensity during colder months (30-60 drops/hour) compared to summer (~ 0-2 drops/hour). Indeed, heavy rainfall events in summer seems to produce no or only slight responses in the drip discharge, which can be explained by the fact that the water is evaporated at the surface and used by vegetation and only lastly for refilling of the soil and epikarst.

While drip loggers count the total number of drops that fall from the roof in the cave, the drops are collected in a bottle for subsequent analysis of water isotopes. Knowing the collected water amount between two visits and the total drip amount over the same period, we estimated drop size diameter on two consecutive 3 month intervals between July 2013 and January 2013. We obtained similar results with respectively drop sizes diameters of 2.769 mm (91855 drops, 1021 grams of water collected) and 2.763 mm (89755 drops, 990.8 grams) for an averaged drop volume of 11.08 mm³ (or ml). This would correspond to a mean discharge of 0.13 ml/s.

4.2 Mean annual surface and cave temperatures

Comparison between cave, soil and atmospheric temperature is shown in Fig. 5 to determine if the cave temperature corresponds to the mean temperature at the surface (Luetscher and Jeannin, 2004). A temperature logger was placed at the M6 drip site location and has recorded cave temperatures from 24th October 2012 and is still running. A one year average (October 2012 - October 2013) shows a mean annual temperature in the cave of 9.8 ± 0.2°C with minimum and maximum temperatures of 9.0°C and 10.2°C, where extremes could probably be due to the opening of the door connecting the show cave and the *Galerie des Fistuleuses* to allow cave CO₂ concentrations to decrease. However, observations document that this has only a minor effect on temperature. For the same period, surface mean annual temperature at Fahy station recorded an average temperature of 8.5°C, slightly colder (ΔT = -1.3 °C) than mean cave temperature. The difference towards warmer temperatures in the cave can be explained by the 200 m elevation difference between the cave (~400 m a.s.l.) and Fahy station (~600 m a.s.l.). Note that earlier temperature monitoring performed between 2008 and 2010 in the same cave gallery (Schmassmann, 2010) showed consistent mean annual values of 9.6°C. Consequently, observations are similar over both monitoring periods and mean annual cave temperature corresponds to the mean annual surface temperature when taking the adiabatic gradient of ~0.0055°Cm⁻¹ (Rolland, 2003) into account.

4.3 Comparison of water isotopes in precipitation, drip water and speleothem fluid inclusions

The potential of Milandre stalagmites can be estimated by comparing fluid inclusion water isotopes to that of the corresponding drip water and amount weighted precipitation. Table 3 summarises δD, δ¹⁷O, δ¹⁸O stable isotopes results and associated secondary order proxies d-excess (d) and ¹⁷O_{excess} (D17) performed in this study. In total 274 analyses of precipitation, 22 “downstream” drip waters, 32 “upstream” cave waters and 8 fluid inclusions (including 4 without δ¹⁷O) were performed.

Isotopes in drip water are integrated over a long period of time (see Section 4.8) and consequently precipitation values must be given in mean weighted delta value form using Eq. 3 to allow comparison with cave drip isotope values:

$$\delta i_{\text{mean weighted}} = (\sum_i \delta_i \times n_i) / (\sum_i n_i) \quad \text{Eq. 3}$$

where δ_i is the daily precipitation isotope value and n_i the daily amount of precipitation. Mean weighted values are given in Table 3. It is noteworthy that a net recharge weighting does not alter the data significantly. Isotope values are always given in brackets in this specific order (δD; δ¹⁸O; δ¹⁷O). Values are sometimes given for seasons: winter (DJF), spring (MAM), summer (JJA) and autumn (SON).

4.3.1 Isotopes in precipitation

Precipitation above Milandre catchment area shows δD_p and $\delta^{18}O_p$ values with a typical local signature comparable to values obtained for Switzerland (Perrin et al., 2003a; Schurch et al., 2003). Fig. 6 summarises all measurements of daily precipitation together with their respective $^{17}O_{excess}$ and d-excess, temperature and relative humidity for Mormont station.

Variability of isotope values in precipitation is high, with values ranging between -1.07‰ and -165.63‰ for δD_p , 3.36‰ and -21.75‰ for $\delta^{18}O_p$ and 1.79‰ and -11.49‰ for $\delta^{17}O_p$ with corresponding mean isotope composition between July 2012 and June 2014 of respectively (-64.97; -9.05; -4.78) ‰. Isotope values show a seasonal sensitivity with enriched values in JJA (-41.17; -6.03; -3.18) ‰ and depleted in DJF (-86.40; -11.82; -6.23) ‰ with corresponding amplitudes (45.2, 5.8; 3.1) ‰. Mormont shows large variations for two consecutive years with a shift of (7.31; 1.37; 0.71) ‰. However, an average of several years show significantly damped variations that do not exceed 0.5‰ in $\delta^{18}O_p$.

CEP stations values are given for comparison and correspond to the transect Basel-Bern-Locarno in Switzerland (Fig. 1 and Fig. 8b). Locarno is located on the southern side of the Alps and presents different climatic settings from Bern and Basel located on the northern side. Basel station is close to Mormont station and presents slightly more negative values of 0.2‰ and 2‰ for $\delta^{18}O_p$ and δD_p respectively.

4.3.2 Isotopes in cave waters

Drip waters show comparable values for all three isotopes between “downstream” drip sites and “upstream” cave waters with overall means of (-60.86 ± 1.74; -8.76 ± 0.25; -4.63 ± 0.13) ‰. Slight differences may have to do with the heterogeneity of the sampling time and natural local variability.

In the monitored chamber, values for M6 (-60.33; -8.73; -4.60) ‰ are integrated over three months (around 1 litre sample), whereas spot values are given for Fi-2 (around 10 to 20 ml samples). They agree well in both δD and $\delta^{18}O$ isotope composition with shifts of 0.58‰ in δD and 0.06‰ in $\delta^{18}O$ over the two years. The overall isotope amplitude measured is 0.4‰ for $\delta^{18}O_{dw}$. A seasonal trend is visible but with two major differences compared to precipitation signal: (i) the signal amplitude is smoothed by a factor of ~25 and (ii) the signal is shifted of several months due to the residence time in the karst (see Section 4.8 for discussion).

In summary, waters sampled at from different cave sites show comparable means, amplitudes as well as standard deviations in their isotopic compositions implying that the precipitation waters are homogeneously mixed in the soil, epikarst and vadose zone above the cave before being transferred to the cave drip sites.

4.3.3 Isotopes in fluid inclusions

For fluid inclusions, results from modern active samples covering the last 40 years have already been partially published (Affolter et al., 2014) and additional measurements are given in Table 2. Speleothem fluid inclusion values for recent samples (-61.3; -8.3; -4.7) ‰ are similar for δD , $\delta^{18}O$ as well as $\delta^{17}O$ to the cave drip water suggesting that signal coming from the cave drip water is faithfully recorded in the speleothem fluid inclusion water and consequently, that ancient inclusions represent relics of past drip water. For early Holocene sample values are slightly more negative but still comparable to today's values.

4.4 Secondary parameters d-excess and $^{17}O_{excess}$ between precipitation and cave drip water

In the daily precipitation samples from Mormont, $^{17}O_{excess}$ values range from -26 to 72 per meg for a two years mean value of 18 per meg (idem for weighted mean) similar to the two years averaged drip water values of 18 and 19 per meg for the M6 and nearby Fi-2 drip sites in the monitored cave chamber. Mean seasonal values are 13 per meg (JJA), 17 per meg (SON), 25 per meg (DJF) and 19 per meg (MAM). During the monitoring period, $^{17}O_{excess}$ shows recurrent trends with rather stable winter values of 27 ± 2 per meg (December 12 – April 13) and 25 ± 4 per meg (November 13 – March 14) and minimum values of 3 per meg for both August 2012 and August 2013. The former may be explained by the rather constant moisture source originated from Atlantic Ocean during winter months (Sodemann and Zubler, 2010). Overall, $^{17}O_{excess}$ shows a monthly amplitude of 40 per meg which is comparable to observations made on a yearly basis at Vostok station in Antarctica (Landais et al., 2012a). In Fig. 6, $^{17}O_{excess}$ is anti-correlated to $\delta^{18}O$ and consequently with site temperature with more positive values in winter (40 per meg) and lower values in summer (0 per meg). Long term $^{17}O_{excess}$ time series records in precipitation are rare or even absent and this especially in low latitudes making the comparison difficult. Nevertheless, a few record are available but mainly in the Polar Regions and there, our observed anticorrelation between $\delta^{18}O$ and $^{17}O_{excess}$ is in opposition with the strong correlation

observed on a limited number of events in Vostok solid precipitation that was explained by change in the kinetic vs. equilibrium fractionation proportion (Landais et al., 2012a), but similar to what was observed in a snow pit at the same station where the anticorrelation between $^{17}\text{O}_{\text{excess}}$ and $\delta^{18}\text{O}$ may be attributed to stratospheric influences (Winkler et al., 2012). Furthermore, our measurements are in agreement with a few measurements in Greenland described in (Landais et al., 2012b). Additionally, in the African monsoon precipitation, (Landais et al., 2010) show also an anticorrelation between δD and $^{17}\text{O}_{\text{excess}}$ measured on a very limited amount of precipitation events.

The relationship between $\ln(\delta^{18}\text{O}/1000+1)$ versus $\ln(\delta^{17}\text{O}/1000+1)$ can help to understand the principle behind the anticorrelation and seasonal variations in $^{17}\text{O}_{\text{excess}}$ by variations in kinetic fractionation. The fractionation factor $\alpha_{\text{equilibrium}}$ (slope) for vapour-liquid water is 0.529 (Barkan and Luz, 2005), whereas the diffusion fractionation (kinetic) factor for water vapour is 0.518 (Barkan and Luz, 2007). Thus, the slope determined in meteoric water is a combination of both equilibrium and kinetic fractionation and the corresponding GMWL for oxygen isotopes has a slope of 0.528 (Luz and Barkan, 2010). In this study based on a two years record, the averaged α_{mean} is 0.5271 (see section 4.7.2) and presents seasonal variations. The fractionation factor is lower in summer (0.5255) than in winter (0.5271), whereas it is 0.5283 and 0.5274 for spring and autumn respectively. It is interesting to see that the α_{mean} corresponds to α_{winter} . It is then possible to formulate an explanation for the anticorrelation between $\delta^{18}\text{O}$ and $^{17}\text{O}_{\text{excess}}$ values by seasonal variations in the kinetic fractionation. Indeed, replacing the fractionation factor α in Eq. 1 for summer (low value) will decrease the $^{17}\text{O}_{\text{excess}}$ values, whereas it is the opposite for winter. Spring values show also a higher $^{17}\text{O}_{\text{excess}}$ than autumn (Fig. 6) but very close to the mean observed value for precipitation. This might indicate that the mean $^{17}\text{O}_{\text{excess}}$ value of about 20 per meg observed in our precipitation may correspond to a mean source effect corresponding, after (Uemura et al., 2010) to a normalized humidity of around 65%, which is, however, rather low compared to measured conditions over the Atlantic region even assuming an sea-air temperature difference of 0.5 to 1 +°C (Singh et al., 2005). Mechanisms responsible to explain these variations should be further studied and include kinetic fractionation during evaporation at the source, during transport, during cloud processes including supersaturation and finally process at the site of precipitation. These mechanisms are complex and involve several meteorological parameters such as humidity conditions, temperature, pressure pattern driving wind fields and strengths, condensation nuclei concentration and its specificity.

To better understand factors influencing $^{17}\text{O}_{\text{excess}}$ parameter at the study site, we evaluate its sensitivity to temperature and relative humidity both at the condensation site and at the main moisture source locations. We used the relative humidity and temperature data from the M6 buoy in the North Atlantic (Irish Weather Buoy Network, 53.07°N/15.88°W, see Fig. 3 for approximate location) located at a distance of roughly 1800 km to determine if any influence of moisture source coming from the Atlantic can be detected in this remote continental location. Based on a 31 days running average, we compare firstly $^{17}\text{O}_{\text{excess}}$ with the temperature or relative humidity. We find that $^{17}\text{O}_{\text{excess}}$ anti-correlates both with temperature at the condensation site ($R^2 = 0.36$) and with sea surface temperature ($R^2 = 0.60$). For the relative humidity, $^{17}\text{O}_{\text{excess}}$ anticorrelates for the Atlantic ($R^2 = 0.22$) but no correlation is observed with local relative humidity ($R^2 = 0.02$) indicating an influence of both temperature and relative humidity of the moisture source. A multiple regression of $^{17}\text{O}_{\text{excess}}$ with the relative humidity and the temperature at Fahy Meteorwiss station gives a correlation of 0.41 (R^2). Adding the relative humidity of the Atlantic source region to the regression analyses, the correlation coefficient increases to 0.61 (R^2), no further improvement is observed when adding the Atlantic source temperature at M6 (0.62). Note, even if the monthly running average may introduce an artificially high correlation, this indicates that oceanic condition at the source (M6 buoy) has an influence on $^{17}\text{O}_{\text{excess}}$ data in NW Switzerland. Further investigations should be made to try to disentangle the influence of individual parameter on the $^{17}\text{O}_{\text{excess}}$ parameter. It is nonetheless worth mentioning that the high correlation with the study site may be the reflection of seasonal covariation of temperature ($R^2 = 0.72$) between the oceanic source and the condensation site, whereas the correlation is low between the respective relative humidity ($R^2 = 0.14$).

Local d-excess shows seasonal fluctuations ranging between -27.96‰ and 21.95‰ around a mean value of 7.41‰ and presents lower d-excess during the summer (~4.7‰) and higher values during the winter (~10.6‰). Overall, d-excess shows a seasonal amplitude of 8‰. Differences can be explained by the origin of moisture during the summer that is mainly continental and probably with local secondary evaporation, whereas during winter it is mainly provided by the Atlantic Ocean (Sodemann and Zubler, 2010). Schotterer et al., (2000) assigned these variations to evaporation conditions at the moisture source, to evaporation of falling rain-drop and evaporation of local soil moisture. Averaged local weighted d-excess is 8.1‰ in precipitation (7.1‰ in summer and 8.1‰ in winter) and slightly lower compared to drip waters with values ranging between 8.9‰ (M6) and 9.5‰ (Fi-2) for the monitored cave chamber. The 1‰ difference between precipitation and drip water is probably due to the buffering in the karst system resulting from the mixing and residence time and consequently the unequal reservoir filling with more water supplies from the cold season.

In summary, $^{17}\text{O}_{\text{excess}}$ signal is kept in the drip water whereas d-excess is ~1‰ depleted. That means that sufficient analytical precision in speleothem fluid inclusion measurements should allow retrieving climate information from both $^{17}\text{O}_{\text{excess}}$ and d-excess from this cave.

4.5 Summary for the monitored chamber

Table 4 summarises the delta values and secondary proxies d-excess and $^{17}\text{O}_{\text{excess}}$ that are of interest for the monitored cave chamber (M6, Fi-2 and M9). The difference between the Mormont weighted mean and the drip water is discussed in Section 4.8. It is worth mentioning here that if the isotope values are weighted using the net recharge (rain – evapotranspiration) at Fahy station, then values (-73.30‰, -10.20‰ and -5.38‰ for δD , $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$, respectively) are still close to the precipitation amount weighted. Drip water and sub-recent speleothem fluid inclusion values are similar for δD , whereas for $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$ values are slightly more negative by 0.4‰ and 0.1‰ respectively but still within the method uncertainty. Nevertheless, the two recent sample measurements made with the Picarro L2140-i show identical values (-60.2; -8.6; -4.7) ‰ as M6 drip site. Thus, no significant differences are found between speleothem fluid inclusion water and modern drip water. Early Holocene values show slightly more negative values. $^{17}\text{O}_{\text{excess}}$ shows the same value in the cave and at the surface while d-excess is 1‰ more positive at surface. In fluid inclusions, $^{17}\text{O}_{\text{excess}}$ is potentially preserved and thus, it would be possible to derive together with the use of the carbon isotope additional information on past biospheric activity (Landais et al., 2007) or past hydrological changes (Schoenemann et al., 2014).

Theoretical values for modern speleothem calcite determined using the relationship of (Friedman and O'Neil, 1977) are not far from the $\delta^{18}\text{O}_c$ measured values (6.5‰). Indeed, a calculated $\delta^{18}\text{O}_c$ value of -7.27‰ is obtained (offset of ~0.8‰) when using the two year $\delta^{18}\text{O}$ averaged drip water isotope value of -8.7‰ and cave temperature of 9.8°C. By doing the same exercise using the most recent empirical relationship based on a large set of cave studies that already take into account a “mean” disequilibrium inherently present in cave environment (Tremaine et al., 2011), a theoretical $\delta^{18}\text{O}_c$ value of -6.85‰ is obtained that is even closer to the measured value meaning that $\delta^{18}\text{O}_c$ precipitates in disequilibrium. It is interesting to note that in B7 cave in east Germany (Niggemann et al., 2003) located around 450 km northward from Milandre cave $\delta^{18}\text{O}$ values of drip water (-8.4‰) and corresponding calcite (-6.3‰) are similar to those observed in Milandre cave.

Good agreement between drip water and the recent fluid inclusion isotope compositions confirms that the cave signal is preserved in speleothems. Nevertheless, hydrogen isotope values seem to be a more conservative proxy for paleoclimate reconstructions than corresponding oxygen, probably because hydrogen has no reservoir for isotope exchange during the transfer in the karst whereas oxygen may exchange continuously with the host calcite of the surrounding rock formation. During isotope measurements, mixing and storage of the isotopes in the soil and epikarst will allow recovering the decadal mean when measuring speleothem fluid inclusions and the annual mean for $\delta^{18}\text{O}$ of the calcite, or potentially seasonal variations. For fluid inclusions this is not an issue since the thickness of samples allows only reconstructions of decadal integrated values in this cave. Indeed, slabs up to 5 mm thick are required for fluid inclusion analysis and consequently the time resolution is dependent on the stalagmite growth speed. For example, the modern part of M6 stalagmite required with an annual growth rate 0.1 mm (laminae counting; Häuselmann et al., 2013) would correspond to a resolution of 40-50 years for fluid inclusion measurements done on a 5 mm slab.

4.6 Factors influencing isotope ratios and relationship to climate

In order to identify the forcing factors of isotope variability, we investigated relationships between atmospheric parameters and isotope values. Correlations (R^2), respectively slopes, are always given in brackets and in this specific order (δD ; $\delta^{18}\text{O}$; $\delta^{17}\text{O}$), respectively (d-excess; $^{17}\text{O}_{\text{excess}}$) for secondary order proxies.

Correlations of water isotopes in precipitations with daily average temperature are lower (0.28; 0.36; 0.30) than for monthly mean precipitation (0.75; 0.73; 0.73) showing clearly the temperature dependence of the site. Corresponding slopes on a monthly basis (3.26; 0.39; 0.22 ‰ / 1°C) are lower than the 0.56‰ / 1°C for $\delta^{18}\text{O}$ observed for the region of Bern during the period 1994 – 2001 (Schurch et al., 2003), but in accordance to the values determined in Basel of 0.34‰ / 1°C for the period 1986 – 2010 which indicates that Basel CEP station is more representative for the Milandre cave area compared to Bern. Low correlations are observed for d-excess and $^{17}\text{O}_{\text{excess}}$ with local temperature on a daily basis (0.04; 0.06) as well as on a monthly basis (0.03; 0.20).

Relative humidity at the precipitation site shows low correlation for all isotopes (0.04; 0.12; 0.04) and a better correlation with monthly mean relative humidity (0.15; 0.17; 0.17). Secondary proxies have no significant correlation both on a daily (0.00; 0.01) and monthly basis (0.08, 0.01). Precipitation amount shows no correlation with all three isotopes both on a daily and on a monthly basis. The d-excess and $^{17}\text{O}_{\text{excess}}$ show insignificant correlation on a daily (0.09; 0.05) and monthly basis (0.15; 0.07).

Seasonality of stable isotopes in precipitation for Switzerland was shown to be correlated to temperature and water vapour pressure with lower values in winter corresponds to depleted isotope values (Schurch et al., 2003) which is confirmed by our observations as water isotopes in precipitation are best correlated with temperature at the condensation site and consequently the dominant effect (Fig. 7 and 3c). When values are integrated on a monthly basis, all three isotopes react in the same way to temperature (~73%) and to relative humidity (~17%), whereas on a daily basis relationships are less robust. The best correlation

for $^{17}\text{O}_{\text{excess}}$ explains 20% of its variation by site temperature. For d-excess a low correlation of 15% is observed with the monthly amount of precipitation.

In Europe, several monitoring studies to understand the relationship between water isotopes in precipitation and corresponding drip waters were recently carried out. Approximately on a North South transect, in Han-sur-Lesse cave (Belgium), van Rampelbergh et al., 2014 found that the temperature effect has a clear influence on the regional water isotope composition in the precipitation with increasing values in summer, similar as observed in this study which is also corroborated with the spatial correlation maps observations (Fig. 3c). Moreover, the water isotope composition of the drip water is constant suggesting a good mixing and a long residence time in the epikarst. Nevertheless, the temperature is not always the driving parameter for $\delta^{18}\text{O}_p$; for instance in Villars cave (South France), (Genty et al., 2014) observed only a weak correlation between surface temperature and $\delta^{18}\text{O}_p$ mainly due to the interaction of different air masses coming from the Atlantic and the Mediterranean Sea. In Molinos cave (North East Spain), (Moreno et al., 2014) observed that temperature and amount of precipitation have an important effect on $\delta^{18}\text{O}_p$ but the source effect (North Atlantic or Western Mediterranean) is dominant on $\delta^{18}\text{O}_p$ due to the location of the cave between the two moisture sources that are North Atlantic and Western Mediterranean that have each a distinct $\delta^{18}\text{O}$ signature. These three European examples illustrate cave to cave variations in water isotope interpretation and thus, the uniqueness of each cave site and the need for specific cave monitoring.

Larger scale atmospheric effects can also have an influence on $\delta^{18}\text{O}_p$ of the study site. The link between $\delta^{18}\text{O}_p$ and the large scale atmospheric patterns such as the NAO for Europe has been investigated by Baldini et al., (2008) who observed that for central European mid-latitudes the NAO index is correlated to the winter $\delta^{18}\text{O}_p$ and was attributed to the strong control of air temperature on $\delta^{18}\text{O}_p$ (Baldini et al., 2008). The NAO is strongly correlated to temperature and precipitation over Europe (Hurrell and Van Loon, 1997) and consequently it has a direct influence on $\delta^{18}\text{O}_p$ through wind dominant patterns and consequently the amount of precipitation and temperature, and this especially in winter (Baldini et al., 2008). Generally, isotopic values are depleted in winter compared to summer months, the influence of NAO on winter months may lead to an increase in precipitation with less negative values that will smooth the annual means. The influence of the North Atlantic Oscillation (NAO) on $\delta^{18}\text{O}_p$ in central Switzerland has been discussed by Teranes and McKenzie (2001). They present paleoclimate reconstructions using sediments of Lake Baldeggersee (central Switzerland, alt. 463 m a.s.l.) based on a modern calibration. The lake is located around 100 km eastward from Milandre cave and it was shown that $\delta^{18}\text{O}_c$ there is mainly driven by temperature but it is also suggested that the NAO may have a discernible influence on the isotopic composition of regional precipitation and that long term trend in the NAO index can explain $\delta^{18}\text{O}_c$ isotopic trends in lake sediments data (Teranes and McKenzie, 2001). Other observations linked the $\delta^{18}\text{O}$ of continental archives with changes in the NAO in central Europe, for alpine ice cores in the Swiss Alps (Schotterer et al., 2002), and even further East, in $\delta^{18}\text{O}_c$ from speleothem from Spannagel cave in Austria (Mangini et al., 2005). More recently, (Luetscher et al., 2015) interprets the isotopic composition in speleothems as a proxy for changes in the North Atlantic storm track during the Last Glacial Maximum in the Sieben Hengste cave systems (Swiss Alps). It is worth noting that for the last three examples, the link between archives and NAO or storm track is observed at high elevations in the Alps which could be due to higher sensitivity of continental archives to NAO index, as for instance suggested for lake sediments in the Western French Alps (Guyard et al., 2013). To have a closer look at the precipitation site data, we investigated the relationships between $\delta^{18}\text{O}_p$ and the NAO index both on a two years interval (daily event basis) at the study site and on a 25 years interval at the CEP station in Basel that recorded $\delta^{18}\text{O}_p$ since 1986 (monthly basis). Results indicate no correlation ($R^2=0.009$) at the study site between daily NAO index and daily $\delta^{18}\text{O}_p$ opposite to what was recently observed in NE Spain (Moreno et al., 2014). This observation seems coherent with regard to the relative distance of the Atlantic moisture source and to the multi-source of moisture air masses (Sodemann and Zubler, 2010). When looking at the correlation between monthly NAO index and $\delta^{18}\text{O}_p$ in Basel for the period 1986 – 2012, no correlation ($R^2=0.0002$) is observed on a monthly basis. For the summer months (JJA), no correlation is observed for both periods with $R^2 = 0.005$ and $R^2 = 0.016$ respectively. Three months seasonal mean show a correlation ($R^2=0.35$) for winter (DJF) and no correlation for summer months JJA ($R^2=0.004$). Teranes and McKenzie (2001) showed that isotope data in Bern and NAO index are in good agreement for the period 1972 – 1995. We observed indeed a high correlation between three months NAO index versus winter (DJF) $\delta^{18}\text{O}_p$ in Basel for the period 1986 – 1995 ($R^2 = 0.75$) in agreement with Baldini et al. (2008), whereas a lower correlation ($R^2=0.28$) is observed for the period 1995-2012. Further investigations would be necessary on Milandre speleothem isotope records to see if such an influence is also detected.

In summary, for NW Switzerland $\delta^{18}\text{O}_p$ is mainly controlled by the temperature at the condensation site (Schurch et al., 2003; this study). Correlation maps between $\delta^{18}\text{O}_p$ and temperature (Fig. 3c) show a significant correlation for central/western Europe and isotopes are related to temperature both on a short (2 years) and on a long interval (25 years). Together with the temperature effect, a discernible influence of large scale atmospheric effects (NAO) on $\delta^{18}\text{O}_p$ is expected (Teranes and McKenzie, 2001) which will mainly have an influence on winter moisture source conditions. A good correlation is observed between the NAO index and the DJF months at the study site but no correlation is seen on a daily precipitation basis. Finally,

for the precipitation amount, no significant correlation is observed either at the study site location on a two year time scale or when comparing with the 25 years CEP Basel station record (Fig. 3c)

4.7 Local meteoric water lines

4.7.1 Local meteoric water line from $\delta^{18}\text{O}$ and δD

The local meteoric water line (LMWL) has been determined for NW Switzerland using the relationship between δD and $\delta^{18}\text{O}$ on daily precipitation samples collected between March 2012 and March 2014. The least square regression equation corresponds to $\delta\text{D} = 7.92 \times \delta^{18}\text{O} + 7.26$ ($R^2 = 0.98$) which is close to the Global Meteoric Water Line (GMWL, $\delta\text{D} = 8 \times \delta^{18}\text{O} + 10$). In addition, winter ($\delta\text{D} = 8.21 \times \delta^{18}\text{O} + 10.62$, $R^2 = 0.98$) and summer ($\delta\text{D} = 7.62 \times \delta^{18}\text{O} + 4.74$, $R^2 = 0.95$) meteoric water lines are shown in Fig. 8. Lower d-excess (4.74‰) and a slightly lower slope indicate evaporation probably mainly occurring in the open gauge used for collection.

Fig. 8 (left panel) summarises all precipitation isotope values produced in this study, whereas Fig. 8 (right panel) shows cave and fluid inclusion waters along with the LMWL and GMWL. Cave waters are close to the LMWL and shifted following the LMWL to more positive values. Eventually, the LMWL will be used for future paleotemperature calculations from speleothem fluid inclusions (e.g. Kim and O'Neil, 1997; Tremaine et al., 2011).

4.7.2 Local meteoric water line from $\delta^{18}\text{O}$ and $\delta^{17}\text{O}$

Relationship between $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ in meteoric waters from NW Switzerland is presented in Fig. 9 together with the relationship for drip waters and specific monitored site location. The slope that relate the local liquid water and vapour at equilibrium (LMWL for oxygen) presents a slope of 0.527 similar to the GMWL for oxygen defined by Luz and Barkan (2010) of 0.528. In cave waters slight variations are observed with a lower slope of 0.518 measured on 40 samples only, but integrated over two years. The cave slope corresponds to the values of terrestrial biospheric exchange (respiration) of Luz and Barkan (2005) with a slope of 0.5179 ± 0.0006 and leaf transpiration slope of Landais et al. (2007).

4.8 Estimation of water transfer time between surface and cave

The transfer time for water infiltrating the soil and epikarst above the cave and its corresponding exit in the M6 soda straw inside the cave was estimated. The estimation of residence time (t) of water in the aquifer for M6 drip site was based on isotope delay between precipitation and drip water. First series of measurements performed with Picarro L1102-i and performed after each field sampling at M6 and Fi-2 drip sites allowed the estimation of a 0.4‰ amplitude (Fig. 10). Re-measurements using a Picarro L2140-i made one to three years after the water sampling do not show a clear seasonality any more in drip water maybe due to sample alteration during storage. Nevertheless, a variation of 0.4‰ in the drip water was used to estimate the residence time of water in the epikarst.

Based on isotope signal transmission through the epikarst, hydrogen (δD) and oxygen ($\delta^{18}\text{O}$) signals are shifted compared to the precipitation signal suggesting a residence time of precipitation waters in the epikarst of around 8 – 10 months. Moreover, the signal is smoothed by a factor of 25. The attenuation is a function of the residence time of the water in the bedrock. As the mean values in drip water are highly smoothed, drip water must represent an integrated surface precipitation close to one year. This suggests that a residence time of 8 – 10 months seems to be possible.

This estimate is corroborated with simple model estimation by comparing the signal amplitude and shift in precipitation and cave water. To estimate the residence time, the seasonal variations have to be taken into account. During the summer, water will preferentially be used by vegetation or evaporated and only partly be stored in the reservoir, whereas during the winter precipitation is infiltrating in the aquifer exhibiting more negative isotope values. Thus, a clear asymmetry between winter and summer infiltration occurs (Fig. 1) and leads to more negative values that are in contrast with the measurements that requires further explanation, which is given the next paragraph. The contribution of different seasonal drip water has to be taken into account and consequently weighted. Eventually, a 10 months mixing associated to a monthly weighted drip rate is able to explain the amplitude smoothing and the temporal shift of the signal in cave drip water. To further investigate the residence time issue, tritium isotope measurements on the collected cave water samples could be performed (Kluge et al., 2010). However, precision may not be sufficient to solve the issue completely.

After crossing the aquifer, the smoothed $\delta^{18}\text{O}$ isotope signal exiting in the cave is 1‰ more positive than in precipitation. This enrichment cannot be explained by isotope variation in precipitation alone, as precipitation values are stable in the range of 0.5‰ within the monitoring time interval. Instead, the enrichment observed in both δD and $\delta^{18}\text{O}$ isotopes may be due to

recycled condensed water inside the aquifer (Luo et al., 2013), but in Milandre cave, evapotranspiration occurring at the surface prior to infiltration is probably sufficient to explain this enrichment. Evaporation processes at the surface will tend to evaporate preferentially lighter water molecules meaning that the heavier ones will infiltrate the aquifer, which leads to isotope enrichment. Already less than 15% evaporated water accounts for the observed isotopic enhancement.

Epikarst storage in Milandre karst aquifer (Perrin et al., 2003b) and infiltration of meteoric waters for the corresponding catchment area (Perrin et al., 2003a) have been carefully described and can be summarised as following: soil and epikarst act as an important groundwater storage of the karst system and/or water circulates slowly in the unsaturated zone. The transit time is long enough for the water to reach equilibrium with calcite and water chemistry is mainly driven by mixing of water derived from different infiltration zones in the epikarst (Williams, 2008). Moreover, Perrin et al. (2003b) observed stable $\delta^{18}\text{O}$ values of $9.15 \pm 0.21\text{‰}$ between June 1999 and July 2000 for waters coming from 15 cave sites. Isotope values showed low variability in time and location, so he defines $\delta^{18}\text{O}$ as a conservative tracer for precipitation flowing out of the cave at Saivu spring (Fig. 1). In this study, $\delta^{18}\text{O}$ “upstream” cave waters are on average $\sim 0.3\text{‰}$ more positive ($-8.83 \pm 0.27\text{‰}$). This enrichment agrees with the trend observed in precipitation from Basel and Bern CEP stations of 0.02‰ year m^{-1} . Indeed, multiplying the trend by 14 years leads to an enrichment of 0.28‰ in precipitation close to the observations made in Milandre cave.

5. Conclusions

Oxygen ($\delta^{17}\text{O}$, $\delta^{18}\text{O}$) and hydrogen (δD) isotope evolution recorded during a two year monitoring period in precipitation, drip water and speleothem fluid inclusions for Milandre cave (NW Switzerland) is presented. Seasonal variations are visible in precipitation with more enriched values in summer and depleted in winter. Water isotopes in NW Switzerland precipitation are mainly controlled by air temperature ($R^2 = 0.73$) on a monthly basis. A low correlation ($R^2 = 0.13$) is observed with local relative humidity, but no correlation is observed with the amount of precipitation. Preliminary observations suggest that influence of large scale atmospheric effects such as NAO on $\delta^{18}\text{O}_p$ occurs mainly during winter months.

Isotope values are enriched by around 10‰ for δD and 1.2‰ for $\delta^{18}\text{O}$ in drip water compared to weighted precipitation values which can be explained by evaporative processes at the surface prior to infiltration in the aquifer. Nevertheless, the isotope signal is smoothed to a high degree due to mixing in the soil and epikarst and of residence time of around 8 – 10 months in the aquifer above the cave. The climatic signal is shifted towards more positive values in drip water and hardly show any seasonality (annual amplitude of 0.4‰) smoothed by a factor of ~ 25 compared to precipitation (annual amplitude of 10‰). Analyses of M6 and M8 stalagmite fluid inclusions coming from the monitored cave chamber showed that the mean annual drip water signal is preserved after its enclosure in speleothem calcite for recent samples allowing speleothem based paleoclimate reconstruction in Milandre cave. The cave located at the border between France and Switzerland presents climate conditions representative for central/western Europe.

After a few adaptations of our measuring line, we successfully performed, for the first time, $\delta^{17}\text{O}$ measurements of fluid inclusion water together with δD and $\delta^{18}\text{O}$ on a single speleothem sample. This analytical advance may allow expanding the speleothem based paleoclimate reconstruction possibilities to the $^{17}\text{O}_{\text{excess}}$ parameter as it has already been done for ice cores (Winkler et al., 2012).

In this study, we showed for the first time that the $\delta^{17}\text{O}$ signal is preserved between precipitation and cave water with the two year monitoring. The secondary parameter $^{17}\text{O}_{\text{excess}}$ shows equivalent averaged values of 18 per meg in both precipitation and drip water. We have shown that $^{17}\text{O}_{\text{excess}}$ results measured in fluid inclusions are roughly comparable to surface precipitation. Extended instrument calibration, as well as the use of several replicates may help obtaining more robust values. These results are promising and retrieving past information about the moisture source based on speleothem fluid inclusions is potentially achievable but more has to be learned. Analytical precision in $\delta^{18}\text{O}_f$ and $\delta^{17}\text{O}_f$ measurements is the key to detecting precise variations in $^{17}\text{O}_{\text{excess}}$.

Investigations of geochemical parameters, the understanding of processes as well as cave accessibility and speleothem richness and preservation allow us to define Milandre cave as a good candidate for paleoclimate reconstructions.

Acknowledgments

We warmly thank Mrs. Anne Forster for sampling daily precipitation water at Mormont MeteoSwiss station. We would also like to thank Pierre-Xavier Meury (Speleo-Club Jura) for field work support in Milandre cave, Peter Nyfeler (Climate and Environmental Physic in Bern) for helpful technical assistance and Sebastian Breitenbach for his valuable comments. We thank MeteoSwiss for their scientific support and for providing meteorological data. We acknowledge three anonymous reviewers for their comments that improved the quality of the manuscript. This study is part of “STALCLIM” and “STALCLIM 2”, Sinergia projects financed through the Swiss National Science Foundation (grant no. CRSI22-132646/1).

Abstract

Central European temperature reconstructions covering the last two millennia are almost entirely based on tree rings and lake sediments. As a result, these temperature reconstructions are seasonally biased and reflect summer rather than mean annual air or cold season temperatures. To fill this gap of knowledge, we reconstructed a highly resolved 2000 year-long speleothem-based oxygen isotope ($\delta^{18}\text{O}$) record from Milandre Cave in the Swiss Jura Mountains. Climate in this region is strongly influenced by westerly air masses, making Milandre Cave an ideal site to record climate variability in the North Atlantic and European realm. $\delta^{18}\text{O}$ variations observed in the stalagmite are attributed to fluctuations in cold season temperature as the aquifer is recharged predominantly between autumn and spring. Calibration using historical temperature unveils temperature variations of nearly 2°C within the past two millennia, with a temperature difference between the warmest decade of the Medieval Climate Anomaly (950–1250 AD) and the coldest decade of the Little Ice Age (1400–1700 AD) amounting to ~1.8°C. Modeled cold season temperatures for the past millennium compare remarkably well with our reconstruction, and confirm the importance of both, solar forcing and internal variability, in driving Central European climate.

1. Introduction

Quantitative climate reconstructions covering the last two millennia are in increasingly high demand to assess the sensitivity of the climate system to anthropogenic and natural forcing and to establish firm links between climatic and societal changes (PAGES, 2009). The ‘2k-Network’ of the IGBP Past Global Changes (PAGES) is aimed at integrating new and existing paleoclimate data, with the goal of generating a global array of regional syntheses of climate variability for the last 2000 years. The rather stable boundary conditions of the climate system during this period (Jones and Mann, 2004; Wanner et al., 2008) allow to study the causes and nature of annual to multi-decadal natural climate variability. It is therefore not surprising that numerous temperature reconstructions covering the last one or two millennia were developed (PAGES 2k Consortium, 2013, and references therein). Yet, most of these reconstructions are based on tree rings and lake sediments and thus biased towards warm season rather than cold season or annual temperatures (e.g., Büntgen et al., 2011; Larocque-Tobler et al., 2012). Thus, paleoclimate records providing information on cold season or mean annual air temperatures are now in high demand by the paleoclimate community.

Central European speleothems are paleoclimate archives with the potential to supply well-dated, highly resolved, and continuous paleoclimate records, which allow reconstructing temperature during the cold season (Mangini et al., 2005; Fohlmeister et al., 2012). Reduced effective infiltration into the karstic aquifer during summer (e.g., Perrin and Kopp, 2005; Wackerbarth et al., 2010) increases the proportion of autumn, winter and spring (AWS hereinafter) precipitation participating in the deposition of speleothem calcite and results in a cold season bias of its oxygen isotopic composition ($\delta^{18}\text{O}$). Here, we present a biannually resolved AWS temperature reconstruction spanning two millennia that is derived from a stalagmite collected in Milandre Cave, Swiss Jura Mountains, in western Central Europe. Stalagmite $\delta^{18}\text{O}$ values are calibrated against regional historical temperature reconstructions to develop a transfer function to calculate absolute AWS temperatures. This record is then compared to various regional to hemispheric climate reconstructions to enhance our understanding of the climate

variability in Central Europe and the North Atlantic-European realm. The Milandre Cave temperature time series is compared to an ensemble of model simulations covering the past millennium to examine the influence of external forcing and internal variability on mid-European AWS temperatures.

2. Milandre Cave: climate and environmental setting

Milandre Cave (47.47°N, 7.02°E, ~500 m asl) is located in the Swiss Jura Mountains (Fig. 1), a region with a semi-continental climate. The prevailing westerly winds transport maritime air to the area and account for year-round precipitation, leading to precipitation of up to 1054 mm yr⁻¹. Accordingly, the moisture in the region is dominated by North Atlantic sources, with occasional contributions from land-recycled moisture during summer (Sodemann and Zubler, 2010). Monthly precipitation averages range from 110 mm in May to 74 mm in January. Mean annual temperature is around 9°C, with mean winter and summer temperatures of 1.1°C and 16.4°C, respectively (meteorological data encompass the period 1960–2011 AD, and are from the nearby weather station Fahy belonging to the Swiss national weather service MeteoSwiss).

The Milandre Cave system encompasses more than 10 km and is part of a karstic aquifer that lies within layers of chalky Rauracian limestone. These are directly underlain by marls that act as an aquiclude (Kovács and Jeannin, 2003). Bedrock thickness above the active part of the karst system varies between 30 and 80 m. There are three known entrances to the cave system, an artificial one at the upstream part of the cave system and two entrances at the downstream part. The latter two are both natural, but were enlarged by speleologists to access the deeper part of Milandre Cave (Gigon and Wenger, 1986). Land use involves pasture, forestry, arable land and some small settlements (Jeannin, 1996; Perrin et al., 2003a). Thickness of prevailing silty loam soils does not exceed a few meters, and infiltration to the aquifer is mainly diffuse through the soil zone (Perrin et al., 2007). The aquifer is drained by a well-developed karstic network consisting of the Milandrine underground river and its tributaries, with a catchment area of ~13 km² (Jeannin, 1996).

Stalagmite M6 was collected in the fossil gallery '*Galerie des Fistuleuses*' (see Fig. 1), situated in a remote part of Milandre Cave, approximately 30 m above the active part and 200 m south of the northern entrance. This part of the cave can be accessed by a 15 m long tunnel, which was mined in 1967 AD. Cave air temperature is 9.9°C and constant throughout the year (± 0.1 °C; monitored in 2012 and 2013), which is close to mean annual air temperature in this region.

Over the last two decades, investigations of the study site provided deep insights into the functioning of the Milandre karst system (e.g., Jeannin, 1996; Perrin, 2003; Perrin et al., 2007; Savoy, 2007), which is essential to reliably interpret proxy records of speleothems.

3. Materials and methods

3.1 . Speleothem description

The candlestick-shaped stalagmite M6 is 182 cm tall and decreases continuously in diameter from about 20 cm at the base to about 5 cm at the top (Fig. 2). M6 developed on the top of a large base stalagmite in an area where it remained unaffected by occasional floodings. The stalagmite was active when collected in autumn 2011, and consists of whitish calcite with no visible organic inclusions and no signs of discontinuities. M6 was fed by a 22 cm soda straw, and the recent fall height amounted to ~1 m. Drip rates at the sampling location vary seasonally between 20 and 200 drips per minute (approx. 0.8 and 8 ml min⁻¹) in summer and winter, respectively (monitored between June 2012 and January 2013). For this study, only the top 52 cm of M6 were analyzed.

A large part of the stalagmite shows couplets of white and porous, and thinner translucent and dense laminae. While the white laminae often show distinct thinning towards the flanks, the translucent laminae exhibit a rather constant thickness. The thickness of the lamina couplets generally decreases with depth, for which reason couplets are increasingly harder to identify in the older portion of the stalagmite.

3.2. Dating and stable isotope analysis

The chronology of stalagmite M6 is based on Uranium-series ages (²³⁰Th hereinafter) and annual lamina counting. ²³⁰Th dating was performed on a multi-collector inductively coupled plasma mass spectrometer (Thermo-Finnigan Neptune) at the Minnesota Isotope Laboratory, University of Minnesota, USA. For the measurements, calcite samples of ~200 mg were collected with a standard dentist drill along the central growth axis. Detailed information on analytical procedures is provided in Fleitmann et al. (2009).

Continuous lamina counting was only possible for the upper 20.5 cm. Counting was conducted on high-resolution scans (4800 dpi) along the central growth axis of the stalagmite.

Stable isotope sampling was conducted along the growth axis using an electronically controlled micromill, at 0.1 mm increments on the top 4.4 cm, and at 0.5 mm increments from 4.5 to 50 cm depth of the stalagmite (150 µg sample weight).

The higher resolved section of the time series was downsampled to 0.5 mm resolution using the linear integration interpolation function in the AnalySeries software (Paillard et al., 1996). Measurements were performed on a Finnigan Delta V Advantage mass spectrometer equipped with an automated carbonate preparation system (Gas Bench II) at the Institute of Geological Sciences, University of Bern, Switzerland. External precision of $\delta^{18}\text{O}$ analyses, upon which the focus is held in this study, is 0.08‰ (1 σ error). All $\delta^{18}\text{O}$ are reported in permil (‰) relative to the international Vienna Pee Dee Belemnite (VPDB) carbonate standard, unless stated otherwise. Further details on the methodology are provided in Fleitmann et al. (2009).

4. Results

The ^{230}Th -dating results for the uppermost 52 cm of stalagmite M6 are provided in Table 1. All ^{230}Th ages are in stratigraphic order, with the deepest sample providing an age of 2077 ± 95 yr BP. The uppermost date at 1.2 cm from the stalagmite top has an age of 41 ± 97 yr BP and thus provides further evidence that M6 was actively growing when collected. Unfortunately, very low concentrations of Uranium (~ 0.05 ppm) and presence of detrital Th result in rather high chronological uncertainties.

The chronology of M6 was improved by counting annual couplets in the upper part, where the ^{230}Th ages were disregarded, and by using the COPRA algorithm (Breitenbach et al., 2012) in the bottom part to establish proxy confidence limits. The resulting median of the 1000 Monte Carlo simulations and its 95% confidence interval represent a robust age model for the bottom part (Fig. 3). As it was not trivial to distinguish between annual and subannual laminae, a conservative uncertainty of 10% of the absolute age was assigned to the lamina chronology. The lamina counts follow the radiometric age model very well and confirm that the couplets are annual in origin. Moreover, they reduce the age uncertainties significantly. In general, growth rates are very high within the top 52 cm and range from 0.14 to 0.50 mm per year.

The oxygen isotope profile (0–50 cm, 1345 values) extends back to 11 BC and its resolution varies between subannual and 4 years (Fig. 6B). $\delta^{18}\text{O}$ values vary between -5.36 and -8.37‰ around a mean of -6.76‰. Superimposed on the long-term trends distinct short-term variations of 1 to 2‰ are observed.

5. Discussion

5.1. Paleoclimatic significance of stalagmite $\delta^{18}\text{O}$ values

Detailed understanding of the modern water-carbonate system in Milandre Cave is essential to reduce uncertainties associated with the interpretation of stalagmite $\delta^{18}\text{O}$ values. This implies that changes in $\delta^{18}\text{O}$ of water along the pathway from precipitation to speleothem calcite must be traced. The following paragraphs provide information on aquifer recharge conditions above Milandre Cave and the principal factors influencing $\delta^{18}\text{O}$ values in precipitation, cave drip water and stalagmite calcite.

5.1.1. Modern climate-precipitation $\delta^{18}\text{O}$ relationship in Switzerland

To determine the climatic factors governing $\delta^{18}\text{O}$ of precipitation ($\delta^{18}\text{O}_p$), we examined the $\delta^{18}\text{O}_p$ time series from Bern (70 km southwest of Milandre Cave), one of the longest in Central Europe (Schürch et al., 2003). Monthly $\delta^{18}\text{O}_p$ values in Bern (1971–2010 AD) are positively correlated with local temperature ($r=0.41$; $p<0.05$; both time series were deseasonalized), with maximum and minimum $\delta^{18}\text{O}_p$ values measured in summer and winter, respectively (Fig. 4). A weekly resolved $\delta^{18}\text{O}_p$ time series above Milandre Cave, measured from September 1999 to January 2002 (Perrin et al., 2003a), is in good agreement with the $\delta^{18}\text{O}_p$ record from Bern, indicating that the latter record is a valid approximation for variations in $\delta^{18}\text{O}_p$ above the cave.

The increase of precipitation-weighted $\delta^{18}\text{O}_p$ with mean annual temperature (MAT), the so-called ‘temperature effect’ (Dansgaard, 1964), amounts to 0.52‰ per 1°C in Bern, which is in good agreement with observed T- $\delta^{18}\text{O}_p$ relationships in the Greater Alpine Region (0.48–0.65‰ per 1°C; Rozanski et al., 1993; Schotterer et al., 2000; 2010) and Europe (0.59 \pm 0.09‰ per 1°C; McDermott et al., 1999). Important for this study, precipitation-weighted $\delta^{18}\text{O}_p$ in Bern and MAT averaged over the northwestern Alps (Auer et al., 2007) are significantly correlated ($r=0.48$; $p<0.05$).

An additional comparison between $\delta^{18}\text{O}_p$ values at Bern and gridded temperature data between 1971 and 2009 AD (CRU TS 3.10; Mitchell and Jones, 2005) reveals highest correlations in regions situated to the west of Switzerland (Fig. 4C), underlining the important role of the westerlies in transporting moisture to Central Europe. This assumption is also supported by isobaric back trajectories, which reveal that the vast majority of the moist air masses associated with heavy precipitation events in western Switzerland (Valais) originate from the North Atlantic (Horton et al., 2012).

Overall, air temperature seems to be the primary parameter influencing $\delta^{18}\text{O}_p$ above Milandre Cave (Siegenthaler and Oeschger, 1980; Schotterer et al., 2000; Schürch et al., 2003; Schotterer et al., 2010).

5.1.2. Groundwater recharge above Milandre Cave

The timing and amount of recharge to the karst aquifer above Milandre Cave is an important control on drip water $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_{dw}$) values. Daily effective infiltration amounts from 1981 to 2011 AD were calculated based on the approach by Jeannin

and Grasso (1995a). As surface runoff is negligible above Milandre Cave (Perrin and Kopp, 2005), effective infiltration I_{eff} can be expressed as where P refers to the amount of precipitation (mm), AET to actual evapotranspiration (mm), and ΔV_{soil} (mm) to variations in soil moisture. For the calculations of I_{eff} , daily precipitation data from the nearby (5 km) MeteoSwiss station Fahy were exploited. In order to calculate AET, potential evapotranspiration (PET) and precipitation are needed, whereas AET is subsequently required to estimate ΔV_{soil} . Although direct measurements of PET were performed at Fahy, they are only of limited use for this study as they were conducted solely for the growing season between 1988 and 1999 AD. However, MeteoSwiss additionally provides estimates of PET for Fahy by applying an empirical approach developed for grassland in Switzerland (Primault, 1962). Because of the high correlation between measured and estimated values ($r=0.91$, $n=72$, $p<0.05$) for PET, MeteoSwiss PET estimates for Fahy are well suited to calculate AET above Milandre Cave.

AET is limited either by the energy available, which is expressed as PET, or by the availability of water (the sum of the daily precipitation amount and the soil water content), for which case AET is lower than PET. Hence, daily values of AET are obtained by taking the minimum value of the two. Importantly, the maximum soil water storage capacity has a large influence on AET and consequently on effective infiltration. When, for instance, the soil stock is incomplete, net precipitation (adjusted for evapotranspiration) first fills the soil before the aquifer is recharged. As defined by Jeannin and Grasso (1995a), a field capacity of 140 mm, a value typical for silty loam, was used. In addition, the daily uptake capacity of the soil was limited to 10 mm of water (Jeannin and Grasso, 1995a), i.e., precipitation exceeding this threshold is directly infiltrated and percolated through the soil zone, independent of the actual soil humidity.

Calculated effective infiltration between 1981 and 2011 AD above Milandre Cave (Fig. 5) indicates that effective infiltration peaks in winter when AET is lowest and soils are saturated. As one would expect, high evapotranspiration in summer leads to soil moisture deficiency and recharge of the karst aquifer is generally low. Hence, a much smaller fraction of the summer precipitation (34%) is effectively infiltrated in comparison to winter precipitation (89%). Overall, 83% of total annual recharge occurs in autumn, winter and spring (AWS). These results compare well with earlier attempts to estimate effective infiltration above Milandre Cave (Jeannin and Grasso, 1995a; Perrin and Kopp, 2005).

To test the accuracy of our calculations, monthly means for effective infiltration above Milandre Cave and discharge of the nearby river Allaine, measured in Boncourt, are compared (data available from www.bafu.admin.ch/hydrology; February 2013). One of the major tributaries of the Allaine is the Milandrine, the underground river of the Milandre Cave system. The strong correlation ($r=0.84$, $p<0.05$) between our calculated time series of effective infiltration above Milandre Cave and discharge of the Allaine adds confidence about the accuracy of our calculations (Fig. 5) as nearly every infiltration peak matches high riverine discharge.

5.1.3. Control on drip water $\delta^{18}O$

$\delta^{18}O_{dw}$ values are controlled by $\delta^{18}O$ of precipitation above the cave site, effective infiltration and various processes in the soil and epikarst (e.g., evaporation). As outlined above, air temperature exerts the strongest influence on $\delta^{18}O_p$ values above Milandre Cave. As only around 55% of total annual rainfall infiltrate into the soil and epikarst (see paragraph 5.1.2 for further details), $\delta^{18}O_{dw}$ values do not reflect the *annual average* isotopic composition of precipitation above Milandre Cave. Although precipitation amounts are higher during summer, the annual mean $\delta^{18}O$ of the seepage in Milandre Cave is slightly more negative than the mean $\delta^{18}O_p$ highlighting the importance of effective infiltration (Perrin et al., 2003a). Moreover, the $\delta^{18}O_{dw}$ signal shows strong buffering confirming the important role of the soil and the epikarst subsystems in mixing, storage and distribution of infiltrated waters (Perrin et al., 2003a; 2003b).

These results confirm observations that the karst aquifer is generally recharged during the cold season and drained in summer (Jeannin and Grasso, 1995a; Jeannin, 1996; Perrin et al., 2003a; Perrin and Kopp, 2005). Preliminary counts of drip rates at the sampling site of stalagmite M6 provide supporting evidence for this assumption, with drip rates being lowest towards the end of the summer (based on ongoing monitoring between June 2012 and January 2013 AD).

5.1.4. Control on stalagmite calcite $\delta^{18}O$

When speleothem calcite is deposited in isotopic equilibrium with parent drip water, calcite $\delta^{18}O$ ($\delta^{18}O_{ct}$) values are primarily influenced by two variables: the $\delta^{18}O$ value of drip water and cave air temperature (McDermott, 2004; Lachniet, 2009). By using modern $\delta^{18}O_{dw}$ values in Milandre Cave, we can test whether calcite was deposited in isotopic equilibrium. Given present-day $\delta^{18}O_{dw}$ of $-8.92 \pm 0.09\text{‰}_{VSMOW}$ and cave air temperatures of 9.9°C , the expected $\delta^{18}O_{ct}$ of -6.51‰_{VPDB} , calculated by applying the fractionation equation given in Coplen (2007), is close to the observed value at the tip of stalagmite M6 ($-6.23 \pm 0.08\text{‰}_{VPDB}$). This indicates that modern calcite is precipitated under conditions close to isotopic equilibrium.

Furthermore, to test whether calcite was deposited in isotopic equilibrium with its parent drip water, we applied the so-called “Hendy test” (Hendy, 1971). Measurements along five growth layers revealed no clear pattern in $\delta^{18}O$ (criterion 1), although variations at layer H2 and H3 exceed 0.5‰ (Fig. 6A). While the same two show a positive correlation between $\delta^{13}C$

and $\delta^{18}\text{O}$ ($p < 0.05$) along their growth layers (criterion 2) suggesting possible kinetic effects, covariation between $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ along the growth axis (criterion 3) is weak ($r = 0.24$, $p < 0.05$). However, any variation towards the flanks of the stalagmite could also result from imprecise sampling, as the integration of different growth layers is practically almost unavoidable (Dorale and Liu, 2009). Moreover, there is increasing evidence that the “Hendy test” may not be a valid control to assess isotopic equilibrium close to the growth axis (e.g., Spötl and Mangini, 2002), where stable isotope profiles are commonly drilled. Instead, greatest confidence can be obtained by replication of $\delta^{18}\text{O}$ time series using contemporaneously deposited speleothems from the same or a nearby cave (Dorale and Liu, 2009; Lachniet, 2009). The annually laminated stalagmite M4, covering the past 185 years (Schmassmann, 2010), was retrieved from a cave passage nearby. It reproduces well within age errors (Fig. 6B) indicating that its evolution predominantly reflects a climatic signal.

The two influencing factors, $\delta^{18}\text{O}_{\text{dw}}$ and cave air temperature through its control on equilibrium fractionation, are expected to act against each other as long-term cooling of the surface climate leads to low $\delta^{18}\text{O}_{\text{ct}}$, whereas concomitant lower cave air temperatures favor the enrichment of ^{18}O in the calcite. In general, variations in $\delta^{18}\text{O}_{\text{dw}}$ of mid-latitude cave sites in Europe tend to outweigh the fractionation effect during calcite precipitation (Lachniet, 2009; McDermott et al., 2011). Furthermore, temperature-dependent variations in $\delta^{18}\text{O}_{\text{p}}$ ($+0.52\text{‰ } ^\circ\text{C}^{-1}$; see section 4.1) are expected to be larger in magnitude than those associated with variations in cave air temperature ($-0.22\text{‰ } ^\circ\text{C}^{-1}$ with temperatures of around 9°C ; Kim and O’Neil et al., 1997), theoretically resulting in a present-day net relationship between $\delta^{18}\text{O}_{\text{ct}}$ and MAT of about $0.3\text{‰ } ^\circ\text{C}^{-1}$.

In summary, we argue that changes in $\delta^{18}\text{O}_{\text{ct}}$ are closely related to changes in $\delta^{18}\text{O}_{\text{dw}}$, which is strongly influenced by temperature-controlled variations in $\delta^{18}\text{O}_{\text{p}}$. As stalagmite M6 captures a direct temperature signal inherent in $\delta^{18}\text{O}_{\text{p}}$, it is very well suited to capture variations in AWS temperature over the last two millennia in Central Europe. This is in contrast to two recently published Holocene speleothem $\delta^{18}\text{O}$ records from Central Europe both exhibiting an inverse $\delta^{18}\text{O}_{\text{p}}$ -temperature relationship. In detail, $\delta^{18}\text{O}$ variations in stalagmites from Spannagel Cave, Austrian Alps, are suggested to reflect variations in the moisture source region (North Atlantic Ocean vs. the Mediterranean Sea) and/or variations in the seasonality of precipitation (Mangini et al., 2005), whereas at Bunker Cave in Western Germany, only the latter effect is expected to be primarily responsible for $\delta^{18}\text{O}_{\text{ct}}$ variations (Fohlmeister et al., 2012). However, the relationship between temperature and seasonality of precipitation on the one hand, and temperature and atmospheric processes on the other hand, are not stable through time (e.g., Casty et al., 2005).

5.2. Temperature calibration of calcite $\delta^{18}\text{O}$ values

Similar to previous attempts to reconstruct temperature from stalagmite $\delta^{18}\text{O}_{\text{ct}}$ values (Frisia et al., 2005; Mangini et al., 2005), gridded historical temperature data (Luterbacher et al., 2004; Xoplaki et al., 2005) were used for the calibration of the M6 $\delta^{18}\text{O}_{\text{ct}}$ values (Fig. 7). To account for the observed cold season bias of effective infiltration above Milandre Cave, the M6 $\delta^{18}\text{O}_{\text{ct}}$ record is calibrated against mean AWS temperature averaged over a broader region ($45\text{--}49.5^\circ\text{N}$, $3\text{--}9^\circ\text{E}$) whose temperature exhibits high correlation to temperature and $\delta^{18}\text{O}_{\text{p}}$ at Bern (Fig. 4C). Before the calibration, the M6 $\delta^{18}\text{O}$ record was fine-tuned within age uncertainties to the temperature curve using AnalySeries (Paillard et al., 1996) (Fig. 7A).

The period between 1680 and 1960 AD was selected as calibration period due to disturbance of cave climate after the mid 1960’s when a tunnel was constructed (Gigon and Wenger, 1986), and increased uncertainties in the temperature reconstruction prior to 1680 AD (Luterbacher et al., 2004; Xoplaki et al., 2005). To develop a transfer function, we compared six intervals of different AWS temperatures with corresponding sections in the M6 $\delta^{18}\text{O}_{\text{ct}}$ record. The coldest interval occurred between about 1685 and 1700 AD coinciding with the late Maunder Minimum with mean cold season temperatures of $3.98 \pm 0.31^\circ\text{C}$. The calcite deposited during this time has the most negative $\delta^{18}\text{O}$ values of the past 500 years ($-7.29 \pm 0.13\text{‰}$) and delivers the first and lowest point on the calibration curve. The second point with a $\delta^{18}\text{O}$ value of $-6.71 \pm 0.10\text{‰}$ corresponds to the subsequent temperature peak around 1720 AD ($4.56 \pm 0.19^\circ\text{C}$). A cold period around 1845 AD ($4.26 \pm 0.17^\circ\text{C}$) corresponds with the last significant advance of Alpine glaciers (Böhm et al., 2001; Casty et al., 2005) and marks the third point on our calibration curve. The corresponding section of the stalagmite exhibits $\delta^{18}\text{O}$ values of $-7.24 \pm 0.12\text{‰}$. A second cold period at the end of the 19th century, when winters were identified as the coldest since 1760 AD in the European Alps (Böhm et al., 2001), delivers the fourth point of the transfer function. During this interval, regional temperature and M6 $\delta^{18}\text{O}_{\text{ct}}$ values averaged $4.42 \pm 0.22^\circ\text{C}$ and $-7.00 \pm 0.17\text{‰}$, respectively. The fifth and highest point marks the period between 1920 and 1960 AD, before the greenhouse gas-induced sharp temperature rise, where constantly high $\delta^{18}\text{O}$ values of $-6.47 \pm 0.06\text{‰}$ correspond to temperatures which are 0.31°C higher than in the average calibration period. The last point of the transfer function averages a relatively stable period between 1755 and 1825 AD, when temperature and $\delta^{18}\text{O}_{\text{ct}}$ amounted to $4.56 \pm 0.01^\circ\text{C}$ and $-6.79 \pm 0.07\text{‰}$, respectively. The linear fit applied to these calibration points represents the transfer function (see Fig. 7B).

The transfer function exhibits a slope of $0.87\text{‰ } ^\circ\text{C}^{-1}$ and reflects the positive correlation between $\delta^{18}\text{O}_{\text{p}}$ and temperature in the mid-latitudes. However, the net slope between $\delta^{18}\text{O}_{\text{ct}}$ and temperature should be considerably lower at around $0.3\text{‰ } ^\circ\text{C}^{-1}$ (see paragraph 5.1.4). Similarly, also Frisia et al. (2005) have observed a significantly higher temperature effect than expected in a stalagmite from the southeastern Alps. The amplified sensitivity of $\delta^{18}\text{O}_{\text{ct}}$ to temperature is remarkable as karst

aquifers are generally associated with attenuation rather than amplification of the isotopic signal (Yonge et al., 1985; Perrin et al., 2003a; 2003b). Furthermore, as calcite was deposited close to isotopic equilibrium with parent drip water, strong kinetic fractionation effects can be ruled out. Although the reason for this discrepancy remains unknown, the close correspondence between historical temperature and $\delta^{18}\text{O}_{\text{ct}}$ over the past 500 years (Fig. 8) and the good fit of the linear model defining the transfer function ($r^2=0.92$) appears to confirm the reliability of the postulated $\delta^{18}\text{O}_{\text{ct}}$ -temperature relationship.

5.3. Temperature variability during the past two millennia

The M6 AWS temperature reconstruction (hereafter referred to as M6T) corresponds remarkably well to regional AWS temperature reconstructions derived from documentary and historical evidence for the region represented by the speleothem proxy (Luterbacher et al., 2004; Xoplaki et al., 2005) and for the Swiss Mittelland (Pfister, 1993), also beyond the calibration period back to 1500 AD (Fig. 8). In the following, the M6T reconstruction is compared to other temperature records of Central Europe and the North Atlantic-European realm. Although comparing records representing different seasons may lead to misinterpretations and can be of somewhat limited informative value, we are convinced that such comparisons help to elucidate the seasonal discrepancies in the temperature evolution.

The M6T record over the last millennium documents generally higher and lower temperatures during the MCA (950–1250 AD) and LIA (1400–1700 AD; as defined by Mann et al., 2009), respectively, a temperature pattern that is in good agreement with numerous climate archives from the North Atlantic realm (Graham et al., 2011, and references therein). Lowest temperatures within the last millennium are observed around 1450 AD, with temperatures well below the ones recorded during the Late Maunder Minimum around 1700 AD. An increase in the relative importance of winter precipitation recharging the aquifer as cause for this distinct minimum in $\delta^{18}\text{O}$ is rather unlikely as summer precipitation in the Swiss Jura Mountains was reconstructed above-average during this period (Magny et al., 2011). Moreover, winter and summer proxy evidence from the Jura Mountains and the European Alps confirm that the mid-15th century was at least as cold as the late 17th century (Mangini et al., 2005; Millet et al., 2009; Larocque-Tobler et al., 2010; Magny et al., 2011; Larocque-Tobler et al., 2012).

Although most of the records in the North Atlantic-European realm show a prolonged warm phase during the MCA, there are notable differences in timing, duration and magnitude of the warming. The maximum in the M6T record at around 1125 AD corresponds well to single-proxy and multi-proxy reconstructions from the European Alps (Mangini et al., 2005; Millet et al., 2009; Büntgen et al., 2011; Trachsel et al., 2012), and to a reconstructed retreat of the Great Aletsch glacier around the first quarter of the 13th century (Holzhauser et al., 2005) considering its response time of 50 to 100 years (Häberli and Holzhauser, 2003). However, the timing of temperature maxima in individual records is not synchronous, which is most likely related to a spatially heterogeneous medieval warming (e.g., Jansen et al., 2007; Diaz et al., 2011), chronological uncertainties of the proxy records, and, most importantly, different seasonal temperature.

The average AWS temperature difference between the LIA and the MCA amounts to 0.48°C in the M6T record, an estimate that is at the lower end of the (summer-biased) MAT difference suggested for the Greater Alpine Region ($0.45\text{--}0.60^\circ\text{C}$), calculated by Mann et al. (2009). The difference between decadal minimum AWS temperature during the LIA and decadal maximum AWS temperature during the MCA (determined by applying 11-yr running averages) is about 1.8°C , which is comparable to the annual SST difference recorded in the North Atlantic off Iceland ($\sim 1.5^\circ\text{C}$; Sicre et al., 2011) and the cold season temperature difference attained in the record of the Austrian Alps ($\sim 1.7^\circ\text{C}$; Mangini et al., 2005), but significantly lower than observed in the Central European summer temperature reconstruction (3.0°C ; Büntgen et al., 2011). The good correspondence to the difference obtained in the cold season temperature record from the Austrian Alps suggests that the calibration is also robust beyond the calibration period, and that summer temperatures reacted more sensitively to the MCA-LIA climate transition.

Between 700 and 900 AD, average temperatures in the M6T record are almost as low as in the 15th century, and clearly lower than for the average LIA. Temperature minima during this interval are also recorded at regional scale (Mangini et al., 2005; Sicre et al., 2011), but temperatures in these reconstructions remained higher than during the LIA. Apart from a short-term cold period in the third century, relatively high temperatures are observed between 0 and 700 AD. Remarkably, the peak warmth at around 550 AD corresponds well with a winter temperature maximum observed in the Austrian Alps (Mangini et al., 2005). However, this contrasts summer-biased climate records from Central Europe, which recorded a period of climate deterioration between about 400 and 700 AD (e.g., Holzhauser et al., 2005; Millet et al., 2009; Büntgen et al., 2011). These discrepancies between winter-sensitive and summer-sensitive proxies may indicate seasonally differing temperature evolution during this period.

In the pre-industrial Holocene, changes in solar activity can be considered as an important climate forcing factor (see Gray et al., 2010 for a review). The correlation between reconstructed solar activity (Steinhilber et al., 2009) (Fig. 8B) and the M6T record is weak ($r=0.17$, $p<0.05$). However, most of the prominent grand minima (Usoskin et al., 2007) and maxima correspond well with short-term (multi-decadal) temperature fluctuations. A temperature depression around 710 AD coincides with one of

the major solar minima. A period of high solar activity between the Oort and Wolf Minimum, also referred to as the Medieval Maximum of sunspot activity (Eddy, 1977), coincides with the well-defined temperature peak in the M6T record at around 1125 AD. Solar activity is generally low during the LIA, coinciding with low temperatures in the temperature reconstruction. The Spörer Minimum defines a long-lasting period (1390–1550 AD) of very low solar activity, corresponding well to the coldest period in M6T. During the Maunder Minimum (1650–1725 AD) reconstructed AWS temperatures show a distinct negative anomaly despite the relatively moderate change in solar irradiance. This confirms the hypothesis that a negative North Atlantic Oscillation (NAO) could have contributed to substantial winter cooling in Central Europe (Wanner et al., 2000; Shindell et al., 2001; Luterbacher et al., 2001; Mangini et al., 2005; Spanghehl et al., 2010). These observations indicate that temperature variations in Central Europe are partly but not exclusively driven by changes in solar irradiance, an observation that is in agreement with previous results on Holocene archives from Central Europe (Niggemann et al., 2003a; 2003b; Mangini et al., 2005; Büntgen et al., 2006; Trachsel et al., 2010; Magny et al., 2011).

The interpretation of volcanic forcing (Fig. 8A) in European paleoclimate records is more complex and spatially and seasonally heterogeneous. Whereas winter-biased continental proxies from Central Europe are expected to record a warming following single volcanic eruptions (Fischer et al., 2007; Zanchettin et al., 2013), a cumulative effect of large volcanic eruptions on climate during certain periods may result in a temperature drop in Europe as global-scale cooling outweighs the regional winter warming effect (e.g., Hegerl et al., 2011). Periods of intensified volcanic activity and decreased solar activity during the 12th and 13th century, together with sea ice-ocean-atmosphere feedbacks, may have contributed to the initiation of the LIA (Miller et al., 2012; Lehner et al., 2013). During the LIA, decreased solar forcing and enhanced volcanic forcing are thought to have contributed to the prolonged cooling (Shindell et al., 2003). Several tropical eruptions during the second half of the 15th century, for instance, may have amplified the impact of the Spörer Minimum leading to the observed temperature minimum in our and other temperature reconstructions.

In addition to natural forcing, internal variability may play an important role in determining climate change, particularly at regional scale (Goosse et al., 2006). General circulation models (GCM) can assist in estimating how much the climate might have been expected to change given the reconstructed forcings in the past, and correspondingly, how much variability might be expected to have arisen from internal variability (Jones and Mann, 2004; Goosse et al., 2005). Thus, comparison between model simulations and the reconstructed temperature may further help to assess the impact of external forcing.

5.3. Inferences from model simulations

Two ensembles of transient simulations were carried out, resulting in monthly temperature estimates for the period 1149–2098 AD (Fig. 9). The simulations were conducted with a coupled GCM, the Community Climate System Model version 3 (CCSM3), which consists of four components: the atmosphere, the ocean, the sea ice, and the land surface (Collins et al., 2006). The time-varying external forcing applied is composed of solar and volcanic forcing, and greenhouse gas concentrations (Hofer et al., 2011). For further information on the climate model the reader is referred to Collins et al. (2006), detailed information about the forcing datasets are provided in Hofer et al. (2011) and Lehner et al. (2012a).

An ensemble of four transient simulations was run from 1500 to 2098 AD using the low-resolution CCSM3, which uses a horizontal atmosphere/land surface grid of approximately 3.75° by 3.75° (Lehner et al., 2012a). Furthermore, an ensemble of six simulations was carried out for the time period 1149–1499 AD using the medium-resolution version resulting in a resolution of about 2.8° by 2.8° (Lehner et al., 2012b). The simulated AWS temperature was averaged over 2x2 grid boxes centered as close to the study site as allowed by the resolution of the model (see Fig. 9D).

On average, between 1149 and 1960 AD, simulated AWS temperatures are about 0.1°C lower than the reconstructed ones (Fig. 9C). This is a remarkably small difference, considering the different regions for which temperature was simulated/reconstructed, and the uncertainties in simulation and reconstruction. Except for the second half of the 20th century, when the greenhouse gas-induced warming is not recorded in stalagmite M6 (likely due to a disturbance of the cave climate), the reconstructed temperature is in good agreement with the ensemble mean. Because of relatively high solar activity, temperatures in the model simulations for the period 1150–1350 AD are generally warmer than during the subsequent LIA when solar forcing was lower. Moreover, the prominent solar minima are also evident in the simulations. Fig. 9B shows the temperature evolution of one selected member of each ensemble in detail. They are in relatively good agreement with our temperature reconstruction besides an apparent offset in the period 1100–1500 AD perhaps related to a systematic bias of the M6 age model in this time interval. Importantly, the ensemble mean allows a more robust interpretation as single members represent only one realization of the possible responses. Indeed, most of the higher-frequency variations of the different ensemble members are relatively heterogeneous, indicating the range of natural variability inherent in the system (Fig. 9A).

In order to address the sensitivity to solar forcing, the M6T record is also compared to the “low solar” CCSM version 4 simulation by Landrum et al. (2013), consisting of a lower magnitude of the solar forcing in comparison to the “medium solar” simulations presented above (Hofer et al., 2011; see Ammann et al., 2007 for the classification of the solar forcing). The long-

term trend of decreasing AWS temperatures during the pre-industrial period of the last millennium and the cold spell during the Spörer Minimum are similarly evident in Landrum et al. (2013), even though the temperature decrease during the LIA is less pronounced. Again, higher frequency variations observed in the temperature reconstruction are not reproduced by the simulation, and are possibly dominated by internal variability.

In summary, the long-term temperature trend and the magnitudes of the transient model simulations compare well with the speleothem $\delta^{18}\text{O}$ -inferred temperature, and confirm that low-frequency variations in solar activity had considerable influence on Central European climate (e.g., Crowley, 2000; Bauer et al., 2003; Goosse et al., 2005; Fernández-Donado et al., 2013). On decadal scales, however, natural variability of the climate system seems to mask the higher frequency variations in solar forcing (e.g., Goosse et al., 2006). Furthermore, rapid transitions, as observed in the aftermath of the MCA, have been suggested to be not solely controlled by simple modifications in radiative forcing, but also by internal variability and feedback mechanisms in the atmosphere or ocean (Wanner et al., 2011, Lehner et al., 2013). Internally generated changes in the NAO or the Atlantic Meridional Overturning Circulation, for instance, are well known to play a determinant role in controlling Central European climate variability (Graham et al., 2011).

5.5. Influence of the North Atlantic Oscillation

The NAO is the dominant mode of atmospheric winter circulation over the North Atlantic and Europe and is characterized by a meridional gradient in the distribution of atmospheric mass over the North Atlantic (Hurrell, 1995; Wanner et al., 2001). While NAO-induced variations in precipitation are well observed over northern and southern Europe, NAO variability in Central Europe is best captured in winter temperature and winter temperature-sensitive $\delta^{18}\text{O}_p$ time series (Wanner et al., 2003; Baldini et al., 2008; Field, 2010; Langebroek et al., 2011; Fohlmeister et al., 2012). It was shown that correlation between winter temperature in Central Europe and the Alps and the winter NAO index is relatively high for the observational era (Wanner et al., 2003; Casty et al., 2005). Moreover, results of Langebroek et al. (2011) suggest that Central European $\delta^{18}\text{O}_p$, as reflected in the stalagmite M6T record, may be even stronger related to atmospheric circulation. This is also confirmed by the good correspondence ($r=0.40$, $p<0.05$) between precipitation-weighted $\delta^{18}\text{O}_p$ above Milandre Cave and the winter NAO index (Fig. 4B). Hence, low-frequency temporal variations in cold season-biased $\delta^{18}\text{O}_{ct}$ -inferred temperature can potentially be used to trace the influence of large-scale changes in atmospheric circulation on Central European climate beyond the instrumental period.

Until today, several NAO reconstructions have been published (summarized by Pinto and Raible, 2012). The longest NAO reconstruction dates back to 1049 AD (Trouet et al., 2009), and uses a speleothem-based precipitation proxy from Scotland (Proctor et al., 2000) and a tree ring-based drought proxy from Morocco (Esper et al., 2007) to account for pressure-induced hydrological changes at both centers of action of the NAO. The M6T record and the proxy-based NAO reconstruction reveal some similar low-frequency patterns over the last millennium (Fig. 10). The persistent positive NAO phase during the MCA, associated with stronger westerlies during the winter season, would provide a dynamical explanation for the observed warmth in our record during medieval times (Trouet et al., 2009). However, the timing of the phase change varies in the two records, and also the short-term fluctuations in our speleothem record do not coincide with the rather stable NAO reconstruction during the MCA. Moreover, the M6 AWS temperature record fails to verify against shorter NAO reconstructions (Luterbacher et al., 2002; Cook et al., 2003) and the longest instrumental winter NAO index (Jones et al., 1997). Furthermore, one single proxy is unlikely to reflect this complex climatic phenomenon reliably due to its susceptibility to spatial changes of the NAO centers of action, which may result in changes of the winter storm tracks and in an inadequate reflection of the NAO signal (Raible et al., 2006; Lehner et al., 2012b). Instead, the NAO variability within the past two millennia is probably best captured by applying a multi-proxy approach. The combination of the two paleorecords used by Trouet et al. (2009) with additional NAO-sensitive proxies in the North Atlantic realm may significantly improve the reconstruction, whose robustness has been questioned recently (Lehner et al., 2012b).

6. Conclusions and Outlook

The temporally high resolved speleothem $\delta^{18}\text{O}$ record from the Swiss Jura Mountains captures variations in AWS temperatures representative for supra-regional climate. The reliability of the two millennia spanning temperature reconstruction is confirmed by the good correspondence to historical temperature reconstructions for the last 500 years. Whereas the lowest temperatures are found during the 8th and 15th century, temperatures at the MCA peak at around 1125 AD were reconstructed to be the highest within the past 2000 years. However, temperatures during the second half of the 20th century are not comparable to the rest of the reconstruction owing to an apparent bias possibly due to the disturbance of cave climate. Comparison to a solar proxy and model simulations indicate that temperature variability is affected by changes in solar forcing, but internal variability plays an important role on decadal scale.

The so far deepest radiometric age in stalagmite M6 (at a depth of 143 cm from totally 182 cm) yields an age of almost 14 ka BP. As there is no sign of any hiatus, the stalagmite provides an invaluable archive for a continuous sub-decadally resolved paleotemperature record back to the last deglaciation.

Acknowledgments

This study was carried out in the framework of the Sinergia project “STALCLIM” funded by the Swiss National Science Foundation (SNSF; grant no. CRSI22-132646/1 to DF). We thank Philipp Häuselmann for his support during the fieldworks at Milandre Cave, and the Spéléo-Club Jura for their collaboration. FL is supported by the National Centre of Competence in Research (NCCR) Climate funded by SNSF. CCR is supported by the Sinergia project FUPSOL of the SNSF (130642). JL acknowledges support from the DFG Project PRIME 2 (PRecipitation In past Millennia in Europe, extension back to Roman time) within the Priority Program ‘INTERDYNAMIK’, from DFG Project “Historical Climatology of the Middle East based on Arabic sources back to AD 800”, and from EU/FP7 project ACQWA (NO212250). The model simulations were performed at the Swiss National Supercomputing Centre (CSCS).

FIGURE CAPTIONS

Figure 1. Location map of Milandre Cave, situated south of the village Boncourt in the Jura Mountains in Central Europe. Subfigure **A** and **B** are from *Atlas der Schweiz*, version 3.0, and subfigure **C** was modified after Perrin et al. (2003a).

Figure 2. Stalagmite M6 from Milandre Cave. This study focuses on the top part of the stalagmite (white frame). Red circles represent locations of dated samples (see Table 1). Section A (blue square) displays a zone with high growth rate where the lamina couplets are well visible.

Figure 3. Age model of stalagmite M6 (0–52 cm). The bottom part is based on seven ^{230}Th ages (black squares with 2σ error; Table 1) that have been used to perform a Monte Carlo (MC) simulation using the COPRA algorithm (Breitenbach et al., 2012). The resulting median (black line) is shown with its 95% uncertainty range (dark gray area). The top part relies on annual lamina counts (red), shown with an assumed 10% counting uncertainty range. The six topmost ^{230}Th ages (white squares), and the associated MC-generated median (dashed line) incl. its 95% confidence level (light gray area) were discarded for the age model due to their high uncertainties relative to the lamina chronology.

Figure 4. Modern relationship between climate and precipitation $\delta^{18}\text{O}$ (1971–2010 AD). **A** Monthly $\delta^{18}\text{O}$ in Bern (black) compared to monthly precipitation-weighted $\delta^{18}\text{O}$ above Milandre Cave (blue; Perrin et al., 2003a) and to monthly temperature in Bern (red). **B** Comparison of annual precipitation-weighted $\delta^{18}\text{O}$ (black) to mean annual temperature (MAT) in Bern (red), and to the winter NAO index (orange; www.cpc.ncep.noaa.gov). **C** Cross-correlation of monthly deseasonalized temperature and monthly precipitation in NW Switzerland (47.25–47.75°N, 6.75–7.25°E; small black square) to monthly gridded deseasonalized temperature and precipitation in Europe (CRU TS 3.10 at 0.5° resolution; Mitchell and Jones, 2005), and correlation of monthly precipitation-weighted and deseasonalized $\delta^{18}\text{O}$ in Bern (black circle) to monthly gridded deseasonalized temperature in Europe. The area specified in the maps (45.0–49.5°N, 3.0–9.0°E) is suggested to be representative for the $\delta^{18}\text{O}_p$ -temperature relationship observed in NW Switzerland. Correlation analysis was performed on the KNMI climate explorer website (climexp.knmi.nl).

Figure 5. Estimated effective infiltration at Milandre Cave (1981–2011 AD). Estimation was carried out using precipitation data (blue) from the MeteoSwiss weather station Fahy, and estimates of actual evapotranspiration (AET) and soil moisture. Monthly discharge amounts of the Allaine (black), measured at the village Boncourt, correspond well with the estimates of effective infiltration (red) confirming the model output. The yellow columns mark the winter seasons.

Figure 6. **A** «Hendy test» results along six different growth layers in stalagmite M6, including correlation analysis between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ along the central growth axis. **B** Replication of $\delta^{18}\text{O}$ between the high-resolution records of stalagmites M6 and M4, sampled in the downstream part of Milandre Cave. The median of the M6 $\delta^{18}\text{O}$ record and its 95% confidence bounds are shown as black line and as gray area, respectively.

Figure 7. **A** Comparison of M6 $\delta^{18}\text{O}$ to regional autumn to spring (AWS) temperatures derived from historical reconstructions (Luterbacher et al., 2004; Xoplaki et al., 2005). Before calibration, the speleothem oxygen record was fine-tuned to the historical temperature reconstructions. ‘R.a.’ stands for ‘running average’. **B** The transfer function between $\delta^{18}\text{O}$ and regional historical temperature has been constructed from six intervals between 1685 and 1960. The dashed lines and the error bars represent the upper and lower 95% confidence limits for the linear fit and the six calibration points, respectively.

Figure 7 (updated). **A** Comparison of M6 $\delta^{18}\text{O}$ (5-years running mean) to regional autumn to spring (AWS) temperatures derived from historical reconstructions (9 year running mean, Luterbacher et al., 2004; Xoplaki et al., 2005) between 1730 and 2011 CE. Before calibration, the speleothem oxygen record was fine-tuned to the historical temperature reconstruction. **B**. The transference function between $\delta^{18}\text{O}$ and the regional historical reconstructions has been constructed with data between 1730 and 1960 CE.

Figure 8. Temperature variability over the past two millennia. **A** Optical depth changes in the visible band due to volcanic aerosols (Crowley, 2000; Hofer et al., 2011) **B** Ice core based reconstruction of total solar irradiance anomaly with reference to (wrt) 1986 AD. (Steinhilber et al., 2009). The yellow bars denote the five grand solar minima of the past 2000 years (Usoskin et al., 2007) **C** $\delta^{18}\text{O}$ -inferred Central European autumn to spring (AWS) temperature (T; 13-sample running average (r.a.) in black) incl. the median (dashed black line) and its 95% confidence limits (gray area). **D** AWS T (25-yr r.a.) averaged over a region indicated by the black square in Fig. 9 (historical; Luterbacher et al., 2004; Xoplaki et al., 2005). **E** Switzerland AWS T (17-yr r.a.; documentary; Pfister, 1993) **F** Austrian Alps winter T (9-sample r.a.; speleothem; Mangini et al., 2005). **G** Central European summer T anomaly wrt 1901–2000 AD (25-yr r.a.; tree-ring width; Büntgen et al., 2011). **H** European Alps summer T anomaly wrt 1901–2000 AD (multi-archive; Trachsel et al., 2012).

Figure 9. Comparison of autumn to spring (AWS) temperature in two ensemble simulations, consisting of six members for 1149–1499 AD (orange; medium-resolution CCSM3) and of four members for 1500–2098 AD (red; low-resolution CCSM3; 2012–2098 AD is not shown), to the M6 $\delta^{18}\text{O}$ -inferred temperature reconstruction (black). **A** The brown curves are the raw data of the simulation, and the colored and black lines represent 13-yr and 13-sample running averages (r.a.), respectively. The median T uncertainty and its 95% confidence bounds are shown as black dashed line and as gray area. **B** M6 AWS temperature

(same curves as in A) compared to selected members (13-yr r.a.). **C** M6 AWS temperature (same curves as in A) compared to the ensemble mean of the two CCSM3 simulations, and to the CCSM4 “low” solar temperature simulation by Landrum et al. (2013) in blue. **D** Map showing the areas over which the simulated temperature was averaged, and the region represented by the M6 temperature record, respectively.

Figure 10. Reconstructed M6 autumn to spring (AWS) temperature (13-sample running average (r.a.) in black, median temperature and its 95% confidence bounds as black dashed line and gray area, respectively) compared to the instrumental winter NAO index from Jones et al. (1997) (31-yr r.a.), representing the pressure difference between Gibraltar and Iceland, and to the reconstructed winter NAO from Luterbacher et al. (2002) (31-yr r.a.) and Trouet et al. (2009).

Erklärung

gemäss Art. 28 Abs. 2 RSL 05

Name/Vorname: Häuselmann Anamaria Diana

Matrikelnummer: 07-103-237

Studiengang: Klimawissenschaften

Bachelor ☐

Master ☐

Dissertation ☐

Titel der Arbeit: Late Quaternary and Holocene paleoclimate and paleoenvironmental reconstruction – a multi-proxy approach on Swiss speleothems

Leiter der Arbeit: Prof. Dr. Dominik Fleitmann

Ich erkläre hiermit, dass ich diese Arbeit selbständig verfasst und keine anderen als die angegebenen Quellen benutzt habe. Alle Stellen, die wörtlich oder sinngemäss aus Quellen entnommen wurden, habe ich als solche gekennzeichnet. Mir ist bekannt, dass andernfalls der Senat gemäss Artikel 36 Absatz 1 Buchstabe o des Gesetzes vom 5. September 1996 über die Universität zum Entzug des auf Grund dieser Arbeit verliehenen Titels berechtigt ist.

Häuselmann Anamaria Diana

Date of birth: 23. 01. 1982 in Bistrita (Romania)

EDUCATION

2011-2015: Dissertation at the Institute of Geological Sciences and Oeschger Centre for Climate Change Research, University of Bern, Switzerland

PhD thesis: Late Quaternary and Holocene paleoclimate and paleoenvironmental reconstruction – a multi-proxy approach on Swiss speleothems

Supervisors: Prof.Dr. Dominik Fleitmann and Prof.Dr. Markus Leuenberger

2007-2010: Major in Pure and Applied Quaternary Sciences at the Institute of Geological Sciences, University of Bern

Master Thesis: Evaluation of geomorphological process rates by combining modern river sediment loads and spatially distributed rainfall data - A study in the catchment of Emme River, Canton of Bern (CH)

Supervisors: Prof.Dr. Fritz Schlunegger and Dr. Oliver Kracht

2002- 2007: Diploma in Engineering Geology at the Babes-Bolyai University Cluj Napoca, Faculty of Biology and Geology, specialization Technical Geology, module Mineralogy

Diploma Thesis: Speleogenesis and Sedimentary Deposits in Cioclovina Cave, Sureanu Mts., Romania

Supervisors: Prof. Dr. Bogdan Onac and Dr. Philipp Häuselmann

1996-2000: Grigore Silasi High School Beclean, specialization accounting-banking

1992-1996: Secondary School, Beclean pe Somes, Romania

1988-1992: Primary School, Beclean pe Somes, Romania

LANGUAGES

Romanian: mother language French: medium level
